Objectives: To develop evidence-based recommendations for clinicians caring for children (including infants, school-aged children, and adolescents) with septic shock and other sepsis-associated organ dysfunction.

Design: A panel of 49 international experts, representing 12 international organizations, as well as three methodologists and three public members was convened. Panel members assembled at key international meetings (for those panel members attending the conference), and a stand-alone meeting was held for all panel members in November 2018. A formal conflict-of-interest policy was developed at the onset of the process and enforced throughout. Teleconferences and electronic-based discussion among the chairs, co-chairs, methodologists, and group heads, as well as within subgroups, served as an integral part of the guideline development process.

Methods: The panel consisted of six subgroups: recognition and management of infection, hemodynamics and resuscitation, ventilation, endocrine and metabolic therapies, adjunctive therapies, and research priorities. We conducted a systematic review for each Population, Intervention, Control, and Outcomes question to identify the best available evidence, statistically summarized the evidence, and then assessed the quality of evidence using the Grading of Recommendations Assessment, Development, and Evaluation approach. We used the evidence-to-decision framework to formulate recommendations as strong or weak, or as a best practice statement. In addition, "in our practice" statements were included when evidence was inconclusive to issue a recommendation, but the panel felt that some guidance based on practice patterns may be appropriate.

Results: The panel provided 77 statements on the management and resuscitation of children with septic shock and other sepsis-associated organ dysfunction. Overall, six were strong recommendations, 52 were weak recommendations, and nine were best-practice statements. For 13 questions, no recommendations could be made; but, for 10 of these, "in our practice" statements were provided. In addition, 49 research priorities were identified.

Conclusions: A large cohort of international experts was able to achieve consensus regarding many recommendations for the best care of children with sepsis, acknowledging that most aspects of care had relatively low quality of evidence resulting in the frequent issuance of weak recommendations. Despite this challenge, these recommendations regarding the management of children with septic shock and other sepsis-associated organ dysfunction provide a foundation for consistent care to improve outcomes and inform future research. (*Pediatr Crit Care Med* 2020; 21:e52–e106)

Key Words: evidence-based medicine; Grading of Recommendations Assessment, Development, and Evaluation criteria; guidelines; infection; pediatrics; sepsis; septic shock; Surviving Sepsis Campaign

Sepsis is a leading cause of morbidity, mortality, and healthcare utilization for children worldwide. Globally, an estimated 22 cases of childhood sepsis per 100,000 person-years and 2,202 cases of neonatal sepsis per 100,000 live births occur, translating into 1.2 million cases of childhood sepsis per year (1). More than 4% of all hospitalized patients less than 18 years and ~8% of patients admitted to PICUs in high-income countries have sepsis (2–6). Mortality for children with sepsis ranges from 4% to as high as 50%, depending on illness severity, risk factors, and geographic location (2, 3, 7–9). The majority of children who die of sepsis suffer from refractory shock and/or multiple organ dysfunction syndrome, with many deaths occurring within the initial 48 to 72 hours of treatment (10–13). Early identification and appropriate resuscitation and management are therefore critical to optimizing outcomes for children with sepsis.

In 2001, the Surviving Sepsis Campaign (SSC) was formed by the Society of Critical Care Medicine (SCCM), European Society of Intensive Care Medicine (ESICM), and the International Sepsis Forum. A primary aim of the SSC was to develop evidenced-based guidelines and recommendations for the resuscitation and management of patients with sepsis. The initial guidelines were published in 2004 and have been reviewed and updated every four years thereafter. Following the 2016 edition, SCCM and ESICM reaffirmed their commitment to evidence-based guidelines for all patients by forming separate task forces dedicated to guidelines for adults and children.

The objective of the SCCM/ESICM “Surviving Sepsis Campaign International Guidelines for the Management of Septic Shock and Sepsis-associated Organ Dysfunction in Children” is to provide guidance for clinicians caring for children (including infants, school-aged children, and adolescents) with septic shock and other sepsis-associated organ dysfunction. We sought to leverage the expertise of a clinical and methodology team to create comprehensive evidence-based recommendations for the recognition and management of children with septic shock or other sepsis-associated acute organ dysfunction. Recommendations from these guidelines are based on the best current evidence but cannot replace the clinician’s decision-making capability when presented with a patient’s unique set of clinical variables. Recommendations are intended to guide “best practice” rather than to establish a treatment algorithm or to define standard of care. These guidelines are appropriate for treating septic shock and other sepsis-associated organ dysfunction in a hospital, emergency, or acute care setting, although some may be applicable elsewhere. Although recommendations were developed without consideration to availability of resources, we acknowledge that variation within and across healthcare systems and geographic regions will determine the practical application of these guidelines.

Although several recommendations for the care of children with sepsis and septic shock have been previously published (14–16), these new guidelines are not intended to update or iterate on these prior documents. Instead, it was the aim of

SCCM/ESICM “Surviving Sepsis Campaign” to provide an evidence-based approach to the management of septic shock and other sepsis-associated organ dysfunction in children using a comprehensive and transparent methodologic approach by a panel with geographic and professional diversity.

METHODOLOGY

Definitions

In 2005, the International Pediatric Sepsis Consensus Conference published definitions and criteria for sepsis, severe sepsis, and septic shock in children based on prevailing views of adult sepsis at the time with modifications for physiology based on age and maturational considerations (17). In 2016, new adult definitions and criteria were published (Sepsis-3) with “sepsis” defined as life-threatening organ dysfunction caused by a dysregulated host response to infection and “septic shock” the subset of sepsis with circulatory and cellular/metabolic dysfunction associated with a higher risk of mortality (18). The term “severe sepsis” was replaced by this new definition of sepsis. Although application of Sepsis-3 to children has been attempted (19, 20), formal revisions to the 2005 pediatric sepsis definitions remain pending (21). Therefore, the majority of studies used to establish evidence for these guidelines referred to the 2005 nomenclature in which severe sepsis was defined as 1) greater than or equal to 2 age-based systemic inflammatory response syndrome (SIRS) criteria, 2) confirmed or suspected invasive infection, and 3) cardiovascular dysfunction, acute respiratory distress syndrome (ARDS), or greater than or equal to 2 noncardiovascular organ system dysfunctions; and septic shock was defined as the subset with cardiovascular dysfunction, which included hypotension, treatment with a vasoactive medication, or impaired perfusion. However, studies that defined sepsis as severe infection leading to life-threatening organ dysfunction were included even if criteria used to define sepsis deviated from the 2005 consensus definitions.

For the purposes of these guidelines, we define septic shock in children as severe infection leading to cardiovascular dysfunction (including hypotension, need for treatment with a vasoactive medication, or impaired perfusion) and “sepsis-associated organ dysfunction” in children as severe infection leading to cardiovascular and/or noncardiovascular organ dysfunction. Because several methods to identify acute organ dysfunction in children are currently available (17, 19, 20, 22, 23), we chose not to require a specific definition or scheme for this purpose.

Scope of Patients

The panel intended these guidelines to apply to all patients from greater than or equal to 37 weeks gestation at birth to 18 years old with severe sepsis or septic shock as defined by the 2005 International Pediatric Sepsis Consensus Conference or inclusive of severe infection leading to life-threatening organ dysfunction. Practically, all infants, children, and adolescents with septic shock or other sepsis-associated acute organ dysfunction are included in this scope. For simplicity, we will

henceforth use the term “children” to refer to infants, school-aged children, and adolescents in these guidelines.

All recommendations apply to children with septic shock and other sepsis-associated acute organ dysfunction unless specific qualifications, such as the subset with immune compromise, are included in the recommendation. Even though these guidelines are not intended to address the management of infection with or without SIRS *when there is not associated acute organ dysfunction*, we recognize that sepsis exists as a spectrum and some children without known acute organ dysfunction may still benefit from similar therapies as those with known organ dysfunction. Finally, acknowledging that neonatal sepsis, especially in premature babies, may have distinct pathology, biology, and therapeutic considerations, newborns less than 37 weeks gestation are excluded from the scope of these guidelines. The panel sought to include term neonates (0–28 d) born at greater than or equal to 37 weeks gestation within the scope of these guidelines because these infants may be recognized and resuscitated outside of a newborn nursery or neonatal ICU. However, because the panel did not specifically address studies of neonates with perinatal infection or conditions that can be associated with neonatal sepsis (e.g., persistent pulmonary hypertension of the newborn), these guidelines do not address all management considerations for neonatal sepsis.

Application of Guidelines by Local Resource Availability

The intended target users of these guidelines are health professionals caring for children with septic shock or other sepsis-associated organ dysfunction in a hospital, emergency, or other acute care setting. However, we acknowledge that many of the recommendations are likely to apply to the care of children with septic shock and other sepsis-associated organ dysfunction across a broad array of settings with adaptation to specific environments and resource availability.

These guidelines were largely developed without consideration of healthcare resources (with some specific exceptions, e.g., fluid resuscitation), although we realize that medical care for children with septic shock and other sepsis-associated organ dysfunction is necessarily carried out within the confines of locally available resources. The panel supports that these guidelines should constitute a general scheme of “best practice,” but that translation to treatment algorithms or bundles and standards of care will need to account for variation in the availability of local healthcare resources. The panel acknowledges as well the need for future research to test the adaptation of interventions to locally available resources.

Funding and Sponsorship

All funding for the development of these guidelines was provided by SCCM and ESICM. In addition, sponsoring organizations provided support for their members’ involvement.

Selection and Organization of Panel Members

The selection of panel members was based on their expertise in specific aspects of pediatric sepsis. Co-chairs and co-vice chairs

were appointed by the SCCM and ESICM governing bodies; panel members were then recommended by the co-chairs and co-vice chairs. Each panel member was required to be a practicing healthcare professional with a focus on the acute and/or emergent care of critically ill children with septic shock or other sepsis-associated acute organ dysfunction. Broad international and multiprofessional representation from critical and intensive care medicine, emergency medicine, anesthesiology, neonatology, and infectious disease with inclusion of physicians, nurses, pharmacists, and advanced practice providers as part of the working group was ensured. Three members from the lay public were also included with a role to ensure that patient, family, and caregivers’ opinions were considered in prioritizing outcomes and finalizing recommendations that the clinicians proposed during the development process. Panelists were recruited from a wide number of countries and healthcare systems, including representation from resource-limited geographic areas. A demographically diverse panel with regard to sex, race, and geography was assembled. Members were then allocated to specific groups based on their expertise.

The methodology team included trained methodologists from McMaster University in Canada (W.A., K.C.) and New York University in the United States (M.E.N.). The team included methodologists with a health research methodology degree (MSc or PhD) and/or advanced methodology training, all of whom are also practicing intensivists. The methodology team provided methodological guidance and leadership throughout the guideline development process.

Question Development and Outcome Prioritization

The panel was divided into groups: 1) recognition and management of infection, 2) hemodynamics and resuscitation, 3) ventilation, 4) endocrine and metabolic therapies, and 5) adjunctive therapies. A sixth subgroup was added to review research priorities in pediatric sepsis.

The co-chairs, co-vice chairs, and group heads made initial selections of the topics. We included topics addressed in the 2016 SSC adult guidelines that were relevant to children, as well as other key pediatric topics discussed in previously published guidelines (14–16). The PICO format, which describes the population (P), intervention (I), control (C), and outcomes (O), was used for all guideline questions. Group heads, panel members, and methodologists reviewed and selected PICO questions considered important to guide care for children with septic shock or other sepsis-associated organ dysfunction. Panel members proposed additional PICO questions of high priority and clinical relevance. For practical reasons, we excluded several issues pertaining to general acute or critical illness that were not specific for sepsis (e.g., head-of-bed positioning during invasive mechanical ventilation) and have been addressed in other guidelines (e.g., Pediatric Acute Lung Injury Consensus Conference [PALICC]) (24). However, topics with particular relevance to children with septic shock or other sepsis-associated acute organ dysfunction were included in this guideline, even if there was evaluation of similar or overlapping topics in previous publications. The final decision

regarding PICO question inclusion was reached by discussion and consensus among the guideline panel leaders with input from panel members and the methodology team in each group.

In adherence with the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) approach, panel members compiled a list of potential outcomes for each PICO question. Subsequently, we electronically surveyed panel members and asked them to rate each outcome on a scale of 1 (not important) to 9 (critically important). We selected only outcomes that were critical (mean of 7 or more) for decision-making, taking a patient's perspective. In addition, we presented all selected outcomes to public members to ask for their input and feedback. The final list of PICO questions is provided in **Supplemental Table 1** (Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

Search Strategy and Evidence Summation

For each PICO question, a professional medical librarian formulated the search strategy with input from the group heads, panel members, and methodologists. Searches utilized a combination of controlled vocabulary (e.g., "sepsis," "bacterial infections," "critical illness," "intensive care units," "pediatrics," "NICU," "PICU," "emergency service") and key words (e.g., "toxic shock," "blood poisoning," "acute infection," "child") in the core search. Additional controlled vocabulary and key words were incorporated to create separate strategies specific to the question posed. Research design filters (e.g., systematic reviews/meta-analyses, randomized controlled trials, observational studies) were also applied as appropriate. Only English language studies were included. No date restrictions were imposed on the searches, but we removed animal-only and opinion pieces from the results. The medical librarian searched a minimum of two major databases (e.g., Cochrane Library, PubMed/MEDLINE, or Embase) to identify relevant systematic reviews, clinical trials, and observational studies published through May 1, 2017. As this was the inaugural version of these guidelines for children, all publications up through May 1, 2017, were considered. Key studies published after the conclusion of the initial literature search on May 1, 2017, were incorporated into the evidence synthesis if identified by panel members as important and relevant even if they were not part of the initial literature review. We excluded articles published in abstract form, in a language other than English, and those focused solely on pre-clinical data. Panel members, with input from methodologists, used the Cochrane risk of bias tool to assess the risk of bias of randomized trials (25) and Newcastle-Ottawa Scale to assess risk of bias of nonrandomized studies (26).

When applicable, the methodologists used meta-analytic techniques to generate pooled estimates across two or more studies. For meta-analysis of randomized clinical trials (RCTs), we used random-effects model and inverse variance method to pool estimates across relevant studies. We reported relative risks (RRs) and 95% CI for binary outcomes, and mean difference (MD) and 95% CI for continuous outcomes. For observational data, we conducted meta-analyses if all individual

studies provided adjusted estimates and included both an intervention and a control arm using a random-effects model and inverse variance method to pool adjusted odds ratio (OR) across relevant studies. All analyses were conducted using RevMan software (Review Manager, Version 5.3; Copenhagen, Denmark).

Formulation of Recommendations

The GRADE approach principles guided the assessment of quality of evidence from high to very low based on six domains: 1) risk of bias, 2) inconsistency, 3) indirectness, 4) imprecision, 5) publication bias, and 6) assessment of the balance between benefit and harm, patients' values and preferences, cost and resources, and feasibility and acceptability of the intervention (27). Methodologists performed initial assessments of quality of evidence and incorporated feedback from panel members to generate final evidence profiles using GRADEpro GDT (28).

The panel initially considered only research focused on pediatric patients using a hierarchy of evidence (**Table 1**). Studies focusing on children with septic shock and other sepsis-associated organ dysfunction were prioritized, although studies inclusive of more general pediatric populations (e.g., all PICU patients) were considered for some questions on a case-by-case basis. If there were no studies or insufficient data in children with sepsis or general pediatric illness, evidence from studies of adult patients was considered using an a priori framework to determine appropriateness of indirect evidence (**Fig. 1**). Evidence from adult studies was generally down-graded due to the indirectness of the evidence.

In a series of webinars, methodologists reviewed the relevant data for each PICO question with panel members to formulate initial recommendations. Each of the groups used the Evidence-to-Decision (EtD) framework to facilitate transition from evidence to the final recommendation. The EtD framework ensured that panel members took into consideration not only the quality of evidence and magnitude of effect but also balance between benefits and harms, patients' values and preferences, resources, cost, acceptability, and feasibility (28).

We classified recommendations as strong or weak using the language "We recommend..." or "We suggest..." respectively. We judged a strong recommendation in favor of an intervention to have desirable effects of adherence that will clearly outweigh the undesirable effects. We judged a weak recommendation in favor of an intervention to have desirable consequences of adherence that will probably outweigh the undesirable consequences, but confidence is diminished either because the quality of evidence was low or the benefits and risks were closely balanced. The implications of calling a recommendation strong or weak are shown in **Table 2**. A strong recommendation does not necessarily imply a standard of care, and circumstances may exist in which a strong recommendation cannot or should not be followed for an individual patient. We permitted strong recommendations "for" an intervention based on low or very low quality of evidence when the intervention had the potential to improve survival and there was low risk for immediate harm. We permitted strong

TABLE 1. Determination of the Quality of Evidence

Underlying methodology
High: Systematic reviews, RCTs
Moderate: Downgraded RCTs or upgraded observational studies
Low: Well-conducted prospective observational cohort studies
Very low: Downgraded observational cohort studies, case-control studies, case series or expert opinion or other evidence
Factors that may decrease the strength of evidence
Methodologic features of available RCTs suggesting high likelihood of bias
Inconsistency of results, including problems with subgroup analyses
Indirectness of evidence (differing population, intervention, control, outcomes, comparison)
Imprecision of results
High likelihood of reporting bias
Factors that may increase the strength of evidence
Large magnitude of effect (direct evidence, relative risk > 2 with no plausible confounders)
Very large magnitude of effect with relative risk > 5 and no threats to validity (by two levels)
Dose-response gradient

RCT = randomized clinical trial.

recommendations “against” an intervention based on low or very low quality of evidence when there was uncertain benefit but very likely or certain harm, including high costs (29).

Best practice statements (BPSs) were developed as ungraded strong recommendations within strict conditions suggested by the GRADE Working Group (**Table 3**) (30). BPS were issued when the evidence could not be summarized or assessed using GRADE methodology, but the benefit or harm was deemed unequivocal. In addition, when evidence was insufficient to make a recommendation, but the panel felt that some guidance based on current practice patterns may be appropriate, we issued an “in our practice” statement. The “in our practice statements” were developed through a survey of panelists to ascertain their state of current practice. As such, “in our practice” statements are intended only to describe current variation in care and are not meant to be construed as recommendations.

As new data are continuously generated, the SSC is committed to ensuring that these guidelines are updated or affirmed every 4 years or sooner if breaking and relevant evidence becomes available.

Voting Process

Panel members convened to review evidence and discuss recommendations in-person and through web conferences. Following

the formulation of initial recommendations through discussion within subgroups, all panelists received links to evidence profiles and polls created using SurveyMonkey (Palo Alto, CA) to indicate agreement, disagreement, or abstention. Only panel members without relevant conflicts of interest could vote. Voters could provide feedback for consideration in revising statements. Panelists also deliberated during face-to-face meetings, during which subgroups presented their draft statements for discussion. Up to three rounds of voting were conducted throughout this process of deliberation in an attempt to achieve final consensus. Acceptance of a statement required votes from 75% of the panel members with an 80% agreement threshold.

A summary of all statements determined by the panel is shown in **Appendix 1**. Evidence summaries and evidence profiles that informed the recommendations are included in the **supplemental tables and figures** (Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Links to specific tables and figures appear within the relevant text.

Conflict of Interest Policy

Conflict-of-interest (COI) disclosures were sought through the SCCM from all panelists and support personnel prior to commencing activities, with updates annually and as needed. The process relied solely on personal disclosure, with clarifications sought when necessary, and centered primarily around potential financial conflicts. The co-vice chairs reviewed all COI disclosures in accordance with SCCM’s standard operating procedures, sought clarification when necessary, and worked with the co-chairs to recommend appropriate recusals. There was no industry input into or support of the guideline development process. No panelists received honoraria for any role in the guidelines process. Only librarians and a supporting project manager received compensation for their work.

Seven individuals were identified with potential COIs, but only three were deemed relevant to the final list of questions included in the scope of this guideline. These individuals were asked to abstain from voting on the final recommendations involving the potential COI. In addition, panel members were asked to voluntarily abstain from voting on final recommendations if they had a potential academic COI (e.g., grant application that could benefit from wording of a particular recommendation), although all panel members were welcome to participate in the group discussions leading up to the final recommendation to ensure that input was available from relevant experts.

SCREENING, DIAGNOSIS, AND SYSTEMATIC MANAGEMENT OF SEPSIS

1) In children who present as acutely unwell, we suggest implementing systematic screening for timely recognition of septic shock and other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence).

Remarks: Systematic screening needs to be tailored to the type of patients, resources, and procedures within each institution. Evaluation for the effectiveness and sustainability of screening should be incorporated as part of this process.

Figure 1. Framework to determine the appropriateness of using indirect evidence from studies of children without sepsis or from adults.

Rationale: Systematic screening for sepsis in children is driven by the premise that earlier recognition will lead to more timely initiation of therapy, which will translate to improved morbidity and/or mortality. Screening tools are designed to increase reliability of sepsis recognition and empower health-care professionals to seek rapid medical review. Rapid recognition of sepsis through standardized screening and procedures to guide management of patients identified as at-risk for sepsis should be an essential component of sepsis quality improvement (QI) programs. Although the optimal method or tool for screening is unclear, we suggest that screening tools be adapted to the type of patients, resources, and processes within each institution.

Several studies demonstrating that institutional sepsis QI efforts improve outcomes have successfully incorporated screening tools (31–37). Most reported sepsis screens were designed to prompt clinicians to prioritize review of patients that had triggered the screen, hence the ultimate decision to treat or not remains with the clinician. Although RCTs have evaluated the role of systematic screening algorithms to recognize clinical deterioration in children more generally (38), high-quality trials on pediatric sepsis recognition are lacking (39), and data are not sufficient to suggest any particular screening tool, although several have been published (40–42) or shared online (<http://www.survivingsepsis.org/Resources/Pages/Protocols-and-Checklists.aspx>). Single-institution studies demonstrate that an electronic health record (EHR)-based screening tool can yield high sensitivity and, when coupled with sequential clinician assessment, improved specificity (43). For facilities that use an EHR, a step-wise approach

combining EHR-triggered alerts followed by clinician assessment has the potential to shorten the time to sepsis recognition (41). Notably, no study was found on systematic sepsis screening in low- and middle-income countries meeting the PICO criteria.

Institutions should monitor and evaluate their practice following implementation of sepsis screening (44). Robust QI balancing measures that should be assessed include clinician response, anchoring bias, increased and/or inappropriate antimicrobial prescriptions, fluid overload, increased PICU admissions and transfers to higher levels of care, and healthcare utilization costs (45). Application of a screening tool requires ongoing optimization of sensitivity and specificity, continuous improvement efforts to maintain provider education and familiarity with the tool, and continual data acquisition to monitor implementation and increase utilization (42). Finally, screening tools must work well with existing or planned other early warning and rapid response systems (46, 47) that may also have inherent limitations (38, 48).

2) We were unable to issue a recommendation about using blood lactate values to stratify children with suspected septic shock or other sepsis-associated organ dysfunction into low- versus high-risk of having septic shock or sepsis. However, in our practice, if lactate levels can be rapidly obtained, we often measure blood lactate in children when evaluating for septic shock and other sepsis-associated organ dysfunction.

TABLE 2. Implications of the Strength of Recommendation

Category	Strength	Quality of Evidence	Implications to Patients	Implications to Clinicians	Implications to Policymakers
Strong recommendation	Strong	Usually high or moderate	Most individuals in this situation would want the recommended course of action, and only a small proportion would not	Most individuals should receive the recommended course of action. Formal decision aids are not likely to be needed to help individuals make decisions consistent with their values and preferences	Can be adapted as policy in most situations, including for use as performance indicators
Weak recommendation	Weak	Any	The majority of individuals in this situation would want the suggested course of action, but many would not	Different choices are likely to be appropriate for different patients, and therapy should be tailored to the individual patient's circumstances, such as patients' or family's values and preferences	Policies will likely be variable
Best practice statement	Strong	Ungraded	Same as strong recommendation	Same as strong recommendation	Same as strong recommendation
In our practice statement	Not a recommendation	NA	NA	NA	NA

NA = not applicable.

TABLE 3. Criteria for Best Practice Statement

Criteria for Best Practice Statement
1) Is the statement clear and actionable?
2) Is the message necessary?
3) Is the net benefit (or harm) unequivocal?
4) Is the evidence difficult to collect and summarize?
5) Is the rationale explicit?
6) Is this better to be formally GRADEd?

Modified from Guyatt et al (30).

Rationale: Blood lactate levels provide a valuable indirect marker of tissue hypoperfusion (49). Although increased lactate levels are not specific, they provide a quantifiable surrogate for tissue hypoxia and can be rapidly obtained by point-of-care tests available in many settings. In adults, blood lactate greater than 2 mmol/L is now included within the operational definition of septic shock as an indication of cellular/metabolic dysfunction, and measurement of lactate is included in the Hour-1 Sepsis Bundle, with recommendations to repeat lactate measurement if the initial value exceeds 2 mmol/L (18, 50, 51). In children, several observational studies have demonstrated an association of elevated blood lactate levels with adverse outcomes in septic shock (11, 52–54). However, the optimal threshold to define “hyperlactatemia” remains unclear. In a PICU study, the mortality rate for children with hypotension requiring vasopressors with lactate greater than 2 mmol/L was 32.0% compared with 16.1% if lactate was less than or equal to 2 mmol/L (11). Other studies

have shown that lactate levels greater than 4 mmol/L are consistently associated with mortality (52). Although blood lactate may be affected by the conditions of the blood draw (e.g., use of a tourniquet), both venous and arterial lactate measurements obtained have been shown to be independently associated with mortality in children (55). In one prospective study in children, normalization of lactate within 2–4 hours of presentation was associated with decreased risk of persistent organ dysfunction (adjusted RR, 0.47; 95% CI, 0.29–0.78) (56). However, no RCTs have tested whether initial or serial measurement of blood lactate directly informs evaluation and/or management in children. Lactate levels should therefore be interpreted as part of a more comprehensive assessment of clinical status and perfusion.

3) We recommend implementing a protocol/guideline for management of children with septic shock or other sepsis-associated organ dysfunction (BPS).

Rationale: Institutional protocols have been shown to improve the speed and reliability of care for children with septic shock or other sepsis-associated organ dysfunction. Studies reported improvements in mortality, length of stay (LOS), duration of organ dysfunction, and development of new or progressive multiple organ dysfunction syndrome (8, 32–34, 36, 57–61). Most of these studies have focused on timely delivery of a “bundle of therapies” (e.g., blood culture, fluid bolus, and antibiotics). For example, an analysis of 1,179 children with sepsis across 54 hospitals in New York State found that completion of a sepsis bundle within 1 hour was associated with lower risk-adjusted OR of in-hospital mortality (0.59; 95% CI, 0.38–0.93; $p = 0.02$) (8). In a recent single-institution study, bundle-compliant care in 1,380 children with septic shock was associated with a five-times lower mortality

(OR, 0.20; 95% CI, 0.07–0.53) (33). In another study, implementation of a sepsis protocol led to a substantial increase in the proportion of children who no longer had organ dysfunction on day 2 after presentation (adjusted OR, 4.2; 95% CI, 1.7–10.4) (34). However, it should be noted that protocols studied to date have variable components, many studies do not report adherence to specific items within protocols, and only a few studies have attempted to adjust for initial illness severity or other patient factors, making it difficult to summarize studies using the GRADE approach. Therefore, because available evidence shows a strong and consistent association that adherence to protocols reduces variability in care and improves outcomes, we recommend implementing a protocol/guideline for management of children with septic shock or other sepsis-associated organ dysfunction as a best practice.

4) We recommend obtaining blood cultures before initiating antimicrobial therapy in situations where this does not substantially delay antimicrobial administration (BPS).

Rationale: Blood cultures remain the most commonly used method to identify bacteremia. Identification of a blood-borne pathogen can have significant clinical implications on the type and duration of antimicrobial therapy and is an important mechanism to recognize multidrug-resistant pathogens (62). Thus, whenever possible, blood cultures should be obtained prior to initiation of antimicrobial therapy in children with severe sepsis or septic shock. Although no studies have directly measured the effect of blood cultures alone on outcome in pediatric sepsis, several observational studies have demonstrated that a bundled approach to initial resuscitation that includes early blood cultures is associated with improved outcomes (8, 31, 33). If collection of the blood cultures is likely to delay administration of antimicrobial therapy to the patient, then administration of antimicrobials should take precedence, in view of the impact of delayed antimicrobial administration on patient outcomes (63). However, because blood cultures may be the only source of information identifying bacterial antibiotic susceptibility, it is important to make all reasonable efforts to collect blood cultures before timely antimicrobial administration. The collection of other biological specimens to identify pathogens from nonblood sites (e.g., urine, cerebrospinal fluid, tracheal aspirate, bronchoalveolar lavage, drainage from collections) should also happen as soon as possible, and depending on the suspected site of infection, such specimens may have a higher yield of pathogen identification than blood cultures. Clinicians should also consider the epidemiology of pediatric infections in relation to age, sex, and host factors, such as comorbidities (64, 65). Specific patterns of pediatric bloodstream infections relating to age and comorbidities are well known, and approximately one out of three bacteremia episodes are associated with organ dysfunction in a recent large population-based study (65).

Limitations of standard blood cultures include the time needed to grow and then identify pathogens and their antibiotic sensitivities, as well as the effect of previous therapy on diagnostic yield. New molecular technologies are becoming

available to facilitate earlier and faster microbiological diagnoses. Such techniques may be able to identify a range of pathogens well before blood cultures are positive (66), and may potentially identify pathogens even after the administration of antimicrobial therapy. However, new molecular diagnostics are currently relatively expensive, are not sufficient for all pathogens and antibiotic sensitivities, and are not universally available.

ANTIMICROBIAL THERAPY

- 5) In children with septic shock, we recommend starting antimicrobial therapy *as soon as possible*, within 1 hour of recognition (strong recommendation, very low quality of evidence).
- 6) In children with sepsis-associated organ dysfunction but without shock, we suggest starting antimicrobial therapy *as soon as possible* after appropriate evaluation, within 3 hours of recognition (weak recommendation, very low quality of evidence).

Rationale: Antimicrobials are the primary medical therapy that directly targets the underlying cause of sepsis, and there is strong biologic rationale for rapid delivery of antimicrobials in patients with sepsis (44). Many QI initiatives have shown improved pediatric sepsis outcomes with implementation of a bundle that includes rapid delivery of IV antimicrobials (8, 32–34, 36, 57–61). Two retrospective observational studies have also demonstrated an association of faster time to antimicrobial therapy with reduced mortality for children with sepsis. The first study was an analysis of 130 children with sepsis (mortality of 12%), including 103 (79%) with septic shock, in which the unadjusted OR for mortality among children with antimicrobials delivered within versus after 60 minutes of sepsis recognition was 0.60 (95% CI, 0.13–2.86) (63). The second study was an analysis of 1,179 children, including 69% with septic shock, where completion of a sepsis bundle within 1 hour of sepsis recognition was associated with decreased mortality (OR, 0.59; 95% CI, 0.38–0.93; $p = 0.02$); however, initiation of antimicrobials alone by 1 hour of recognition was not associated with significant mortality reduction (OR, 0.78; 95% CI, 0.55–1.12; $p = 0.18$) (8). When the adjusted OR of these two studies were pooled, there was a possible reduction in mortality (OR, 0.77; 95% CI, 0.55–1.08) (**Supplemental Table 2** and **Supplemental Fig. 1**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Other secondary endpoints reported in the literature have also been associated with shorter time to initiation of antimicrobial therapy, including reduced LOS, shorter duration of organ dysfunction, and reduced development of new or progressive multiple organ dysfunction syndrome (8, 32–34, 36, 57–61). Furthermore, indirect evidence from adult sepsis generally supports a benefit to starting antimicrobial therapy as soon as possible after recognition of septic shock (67–72). Thus, timely antimicrobial therapy—ideally administered as part of a more comprehensive bundle of initial care—should be the goal for children with septic shock.

The definition of “timely” in this context represents an area of controversy relating to challenges in the accurate recognition of patients with sepsis and septic shock and the need to consider balancing QI metrics such as unnecessary antimicrobial usage (44, 73, 74). One pediatric study (63) indicated a dose-response gradient such that the longer time to antimicrobial therapy, the higher the mortality. Yet the mortality increase reached significance only when antimicrobials were administered greater than 3 hours in comparison to less than 3 hours, whereas the mortality of patients receiving antimicrobials within less than 1 hour was not different from those receiving antimicrobials within less than 3 hours in that relatively small study. The second, larger pediatric study demonstrated a significant decrease in mortality if antimicrobials were administered within 1 hour, but only in the context of a bundle that included a blood culture and fluid bolus (8). Thus, available pediatric studies do not provide a clear time cutoff after which the risk of mortality or other adverse outcomes increases, but rather support that there is likely to be an incremental risk for harm as time to antimicrobial initiation increases, in particular beyond 3 hours. Notably, the benefit of antimicrobial therapy within 1 hour of recognition has been most prominent in cohorts with a predominance of septic shock (as compared with sepsis without shock) patients (8, 63).

Based on limited pediatric evidence and indirect evidence from adult studies, the panel supported that, in children “with septic shock,” antimicrobial therapy should be initiated as soon as possible and ideally within 1 hour of recognition. Suspicion of septic shock can usually be guided by clinical findings rapidly ascertained through history and physical examination. Although our recommendation to ideally administer antimicrobial administration within 1 hour of recognition of septic shock establishes a tangible goal that emphasizes the importance of early antimicrobial therapy and assists clinicians in prioritizing bedside care, this cut-point should not be misconstrued as a known biological truth. Thus, dichotomous time-based metrics of the quality of care for children with sepsis, while pragmatic and potentially useful to trend, may be of less value than use of continuous variables such as median time to antimicrobials. Despite a very low quality of evidence on this topic, we provide a strong recommendation because the panel concluded that most patients would accept and most clinicians should seek to initiate antimicrobial therapy as soon as possible after recognition of septic shock in most situations.

For children “without clinical signs of shock,” the panel acknowledged that the diagnosis of sepsis-associated organ dysfunction has additional challenges related to the need to discriminate those with true sepsis from among a large number presenting with suspected infection (44). In view of the available evidence, we suggest starting antimicrobial therapy as soon as possible after sepsis recognition, while allowing up to 3 hours for appropriate diagnostic investigation for patients without clinical signs of shock and for those with an uncertain diagnosis. However, the diagnostic evaluation should be performed expeditiously and, if and when the evaluation supports a likely infection or evidence of septic shock or other

sepsis-associated organ dysfunction becomes manifest, antimicrobial therapy should be immediately administered.

- 7) We recommend empiric broad-spectrum therapy with one or more antimicrobials to cover all likely pathogens (BPS).
- 8) Once the pathogen(s) and sensitivities are available, we recommend narrowing empiric antimicrobial therapy coverage (BPS).
- 9) If no pathogen is identified, we recommend narrowing or stopping empiric antimicrobial therapy according to clinical presentation, site of infection, host risk factors, and adequacy of clinical improvement in discussion with infectious disease and/or microbiological expert advice (BPS).

Rationale: Sepsis mortality is associated with delays to “appropriate” antimicrobial therapy, and hence optimal treatment for sepsis relies on accurate selection of antimicrobials to ensure activity against the major pathogens (50, 63, 70, 75). “Empiric therapy” refers to the initial choice of antimicrobials pending microbiological results (Table 4) and is based on the predicted likelihood of bacterial pathogens. Empiric therapy should cover a broad range of pathogens that are likely to cause the infection, acknowledging that, in rare circumstances, this may not fully cover very unusual pathogens. “Broad-spectrum therapy” refers to the use of “single- or multi-drug” antimicrobial therapy with activity against multiple groups of bacteria/pathogens. Broad-spectrum therapy is recommended for initial empiric therapy of children with septic shock or sepsis-associated organ dysfunction to increase the likelihood that the initial empirical therapy is effective against the causative pathogens.

The initial choice of empiric antimicrobials should take into account the specific clinical history (e.g., age, site of infection, concomitant disease states, comorbid conditions, indwelling devices). Patients with recent or current hospital exposure should receive empiric therapy that considers known infection or colonization, as well as any recent antimicrobial exposure. Institutions or regions should identify the most appropriate first-line single-agent antimicrobial, taking into account anatomic site of infection, age, local epidemiology, and host comorbidity and risk factors (e.g., ceftriaxone is recommended for community-acquired sepsis by the National Institute for Health and Care Excellence [NICE] in the United Kingdom) (16). For complex patients or those recently or currently in hospital, the choice of empiric antimicrobials should also take into account concomitant underlying diseases, chronic organ failure, indwelling devices, the presence of immunosuppression or other form of immunocompromise, recent known infection or colonization with specific pathogens, and recent receipt of antimicrobials (65, 76, 77). When available, an infectious diseases clinician should be consulted. Other nonbacterial pathogens that are suspected as a cause of infection should also be targeted as part of initial antimicrobial therapy on a case-by-case basis.

Sepsis in children is most commonly due to gram-negative or gram-positive bacteria, although the relative prevalence of these pathogens varies by age, geographic region, location (community vs hospital) of sepsis onset, and other patient

TABLE 4. Definitions for Empiric, Targeted/Definitive, Broad-Spectrum, and Multiple Drug Antimicrobial Therapy

Term	Definition	Comment
Empiric antimicrobial therapy	Initial antimicrobial therapy started for suspected infection in the absence of definitive microbiologic pathogen identification	Empiric therapy may consist of single or multiple agents but should be broad spectrum in nature. Empiric antimicrobial therapy should be based on local, regional, or national pathogen epidemiology and patient risk factors
Targeted/definitive antimicrobial therapy	Antimicrobial therapy targeted to specific pathogen(s), usually after microbiologic identification	Targeted/definitive therapy may consist of single or multiple agents, but should not be broader than required to treat the specific pathogen(s) after microbiologic identification
Broad-spectrum antimicrobial therapy	An antimicrobial regimen with activity against multiple different groups of bacteria or other pathogens considered to be likely causes of the clinical presentation	Broad-spectrum antimicrobial therapy may consist of single or multiple agents
Multiple-drug antimicrobial therapy	More than one antimicrobial agent is needed to either 1) expand the spectrum of coverage to include additional pathogens (e.g., vancomycin for methicillin-resistant <i>Staphylococcus aureus</i> ; 2) decrease the likelihood of resistance to any particular single agent (e.g., for patients with known or high-risk for multi-drug resistant organism); or 3) provide synergy to treat a suspected or known pathogen	

factors. Invasive fungal infections are largely restricted to immunocompromised patients and preterm infants. Certain specific conditions put patients at risk for atypical or resistant pathogens, thus requiring specific empiric regimens. For example, neutropenic patients are at risk for an especially wide range of potential pathogens, including resistant gram-negative bacilli and *Candida* species, and neonates are at risk for sepsis caused by *Listeria monocytogenes* and disseminated herpes simplex virus (HSV). Children with chronic conditions treated in hospital settings are prone to sepsis with resistant bacteria such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci. For children at risk for multidrug-resistant bacterial infections, empiric broad-spectrum antimicrobial regimens may require more than one agent to broadly cover such potential pathogens.

For specific empiric broad-spectrum antimicrobial therapy, the reader is directed to published resources (76, 78) and the need to consider patient history, allergies, local epidemiology, and suspected site/source of infection. However, general suggestions can be provided here. For previously healthy children with community-acquired sepsis, a third-generation cephalosporin (e.g., ceftriaxone) may be sufficient. Vancomycin should be added in settings where MRSA or ceftriaxone-resistant pneumococci are prevalent, and addition of an aminoglycoside or substitution of a carbapenem is appropriate in settings where ceftriaxone resistance is common in gram-negative bacteria (79). For immunocompromised patients or hospital-acquired sepsis, antimicrobial therapy should begin with an anti-pseudomonal third- or higher-generation cephalosporin (e.g., cefepime), a broad-spectrum carbapenem (e.g., meropenem, imipenem/cilastatin), or an extended-range

penicillin/ β -lactamase inhibitor combination (e.g., piperacillin/tazobactam) (78). For neonates, therapy should also include ampicillin for listeria and consideration for empiric acyclovir if there is a clinical concern for HSV (76). For patients with a suspected or documented intra-abdominal source of infection, therapy should include broad coverage for gastrointestinal pathogens, including anaerobic bacteria, with either an extended-range penicillin/ β -lactamase inhibitor combination or carbapenem, or addition of clindamycin or metronidazole. For patients who present with sepsis complicating an influenza-like illness during the local influenza season, empiric antiviral therapy should be started while awaiting the respiratory virus testing (80, 81). Patients at higher risk of antibiotic-resistant infection because of past infection or colonization, local epidemiology, or recent broad-spectrum antibiotic use should receive an individually tailored empiric therapeutic regimen (82). In cases of suspected toxic shock syndrome or necrotizing fasciitis, empiric treatment should include clindamycin or lincomycin to limit toxin production and enhance bacterial clearance (83). Finally, for sepsis treated in regions endemic for rickettsial or parasitic pathogens (e.g., malaria), clinicians should consider adding relevant empiric coverage.

“Targeted or definitive therapy” refers to the antimicrobial regimen targeted to a specific pathogen(s) after microbiologic identification. As with empiric therapy, targeted/definitive therapy may be single- or multi-drug therapy, but should not be broader than required to treat the specific pathogen(s) after microbiologic identification (84, 85). Risks of unnecessary continuation of broad-spectrum antibiotic and other antimicrobial therapy include direct side effects and toxicities (such as the nephrotoxicity or ototoxicity of aminoglycosides),

infection with *Clostridioides difficile* (formerly *Clostridium*) or fungal pathogens, and promotion of antimicrobial resistance in the patient and in the community. In addition, unnecessary exposure to antibiotics may lead to alteration of the human microbiome early in life, the impact of which is poorly understood but has been associated with worse outcomes such as necrotizing enterocolitis in newborns.

Because most microbiological cultures show significant growth within 24 to 36 hours of collection when a pathogen is present (86), empiric treatment should be reevaluated after no more than 48 hours following initiation. If no pathogen is identified and bacterial/fungal infection is deemed unlikely, clinicians should stop empiric antimicrobial therapy to reduce unnecessary exposure to antibiotics/antifungals. However, many children with a clinical diagnosis of septic shock do not have a pathogen isolated (5, 6). Patients with negative bacterial microbiological results may have false-negative tests due to antibiotic pretreatment, absence of bacteremia (e.g., bacterial pneumonia despite true bacterial infection), or sepsis-related to viral infections (87). Thus, the decision to continue, narrow, or stop antimicrobial therapy must often be made on the basis of clinician judgment and indirect clinical information, taking into account the clinical presentation, site and type of infection, host risk factors, and adequacy of clinical improvement. Complex patients should be discussed with pediatric infectious diseases and/or microbiology specialists to ensure likely pathogens are treated and that antibiotics and other antimicrobials are stopped when they are no longer necessary.

10) In children without immune compromise and without high risk for multidrug-resistant pathogens, we suggest against the routine use of empiric multiple antimicrobials directed against the same pathogen for the purpose of synergy (weak recommendation, very low quality of evidence).

Remarks: In certain situations, such as confirmed or strongly suspected group B streptococcal sepsis, use of empiric multiple antimicrobials directed against the same pathogen for the purpose of synergy may be indicated.

11) In children with immune compromise and/or at high risk for multidrug-resistant pathogens, we suggest using empiric multi-drug therapy when septic shock or other sepsis-associated organ dysfunction is present/suspected (weak recommendation, very low quality of evidence).

Rationale: The selection of an empiric antimicrobial regimen requires consideration of a patient's underlying disease state, potential history of prior infections and colonization with multidrug-resistant organisms, presence of immunosuppression, and possible recent antimicrobial use, as well as local pathogen prevalence and susceptibility profile (50, 88, 89). Empiric therapy may be single- or multi-drug, but should be broad spectrum in nature as defined in Table 4. For select patients or with concern for particular types of infection, this may necessitate adding a glycopeptide (i.e., vancomycin) to ensure empiric coverage of MRSA or a second gram-negative agent (e.g., aminoglycoside in addition to a beta-lactam or second/third-generation

cephalosporin) when antibiotic resistance is a concern. However, routinely including an aminoglycoside or a glycopeptide for synergy or "double-coverage" as part of an empiric regimen is not supported by the available data (89–100).

A recent Cochrane review evaluated beta-lactam monotherapy versus beta-lactam and aminoglycoside combination regimens for sepsis and included 69 trials accounting for 7,863 participants, including neonatal and pediatric patients (88). In trials where the mono- and multidrug arm used the same beta-lactam, no difference in clinical outcomes was observed between study groups. In studies where the monotherapy arm contained a beta-lactam of broader spectrum than the multi-drug arm, monotherapy showed a possible benefit for all-cause mortality (OR, 0.85; 95% CI, 0.71–1.01) and a significant advantage for clinical failure (OR, 0.75; 95% CI, 0.67–0.84) (88). Additionally, indirect evidence from adults with sepsis including 13 RCTs comparing empirical mono- versus combination antibiotic therapy suggests mortality and other outcomes are not improved by empiric combination therapy (90). Therefore, many children with septic shock and other sepsis-associated organ dysfunction do not require empiric multi-drug therapy. Clinicians should continually reevaluate the local epidemiology and resistance rates to ensure monotherapy remains appropriate (88).

Certain clinical scenarios, however, may necessitate multi-drug antimicrobial therapy. For example, in patients at high risk for resistant gram-negative infections with sepsis, combining a beta-lactam/beta-lactamase inhibitor agent (i.e., piperacillin/tazobactam combination) with an aminoglycoside (i.e., gentamicin) can be considered, not for synergy, but for expanded coverage to treat both susceptible and resistant pathogens until final identification and susceptibilities are known (101–103). Additionally, a synergistic multi-drug regimen may be appropriate in select settings, even for targeted/definitive therapy, such as device-associated infections, enterococcal endocarditis, staphylococcal endocarditis, group B streptococcal sepsis, and carbapenem-resistant Enterobacteriaceae infections (104, 105).

Pediatric patients with cancer and transplant recipients have a substantial degree of immunosuppression and represent a population at higher risk for colonization and infection with multi-drug resistant organisms (106, 107). The 2017 guidelines for the management of fever and neutropenia (FN) in children with cancer and hematopoietic stem-cell transplantation recommended monotherapy with an anti-pseudomonas beta-lactam, a fourth-generation cephalosporin, or a carbapenem as empiric therapy in high-risk pediatric patients with FN (78). The three RCTs in high-risk pediatric FN comparing monotherapy with aminoglycoside-containing combination therapy found no significant differences in failure rates, infection-related mortality, or overall mortality (78, 108, 109). The meta-analysis also confirmed the efficacy and safety of monotherapy without the addition of an aminoglycoside. However, the 2017 guidelines on the management of children with FN did recommend addition of a second gram-negative agent and/or a glycopeptide when resistant organisms were

suspected for patients who are clinically unstable (i.e., septic shock) and in centers with a high rate of resistant pathogens (78). Therefore, for children with septic shock or other sepsis-associated organ dysfunction who have immune compromise and/or are at high risk for multidrug-resistant pathogens, we suggest empiric multi-drug therapy.

Currently, specific resistance rate thresholds do not exist to help clinicians decide when the addition of a glycopeptide or second gram-negative agent for sepsis or septic shock is necessary. The U.S. guidelines for the management of community-acquired pneumonia in adults suggest a 25% rate of high-level macrolide resistance in the community as the threshold beyond which macrolides should not be used (110, 111). Additionally, current guidelines from the Infectious Diseases Society of America recommend an alternative antibiotic for skin and soft tissue infections if the local clindamycin resistance rate is greater than 10% (112). Considering the current rates of morbidity and mortality for patients with sepsis or septic shock, a local or regional antimicrobial resistance rate exceeding 10% is probably a prudent threshold for the addition of a second agent if that pathogen is suspected (5, 63).

12) We recommend using antimicrobial dosing strategies that have been optimized based on published pharmacokinetic/pharmacodynamic principles and with consideration of specific drug properties (BPS).

Rationale: Sepsis may alter the pharmacokinetics and pharmacodynamics of antimicrobials. Therefore, antimicrobial dosing should be individualized to deliver effective and timely treatment of life-threatening infection, while at the same time limiting adverse medication effects. Sub-therapeutic dosing can lead to failure to clear the infection, prolong organ dysfunction, and can lead to the development of antimicrobial resistance. A substantial proportion of sepsis patients are at risk for altered drug metabolism and/or clearance, including those with kidney and hepatic dysfunction and those treated with extracorporeal therapies (113). In particular, continuous renal replacement therapy (CRRT) and extracorporeal membrane oxygenation (ECMO) both lead to profound alteration of antimicrobial clearance, requiring individual dose adaptation (114). Therapeutic drug monitoring, where available, can permit individualized antimicrobial dosing to achieve maximal effect while minimizing toxicity (115).

Examples of sepsis and septic shock-related altered pharmacokinetics include increased volume of distribution as a result of fluid therapy and capillary leak (116), decreased antimicrobial clearance as a result of altered renal and hepatic organ perfusion and organ dysfunction (117), and higher unbound drug levels due to hypoalbuminemia leading to increased clearance (118). Hepatic dysfunction impairs the metabolism of lipophilic and highly albumin-bound antibiotics, leading to drug accumulation and toxicity. In renal dysfunction, time-dependent antibiotics cleared by the kidneys, such as the beta-lactams, require reduced dosing frequency.

The three main determinants of antimicrobial efficacy are 1) the time during which the concentration of the drug

remains above the minimum inhibitory concentration (MIC) of the causative pathogen ($T > MIC$) (time-dependent antibiotics); 2) the peak concentration to MIC ratio (C_{max}/MIC) (concentration-dependent antibiotics); and 3) the ratio of the 24-hour area under the concentration-time curve divided by the MIC (AUC_{24}/MIC) (concentration-dependent with time-dependence antibiotics). The main classes of time-dependent antibiotics include beta-lactams (penicillins, cephalosporins, carbapenems, monobactams) and lincosamides (clindamycin and lincomycin). For amoxicillin-clavulanic acid, current published dosing regimens in critically ill children can result in sub-therapeutic concentrations in the early period of sepsis due to augmented renal clearance (119, 120). In sepsis, the use of continuous or extended infusions with loading doses, as opposed to intermittent dosing, may lead to improved outcomes in patients treated with beta-lactam antibiotics (121).

The main classes of concentration-dependent antibiotics include aminoglycosides and metronidazole. In some centers, drug concentrations measured within 60 minutes before or after administration of aminoglycosides are used to estimate the C_{min} and C_{max} , respectively, and together with the MIC of the pathogen, can help to guide appropriate antimicrobial dosing (118). Concentration-dependent antibiotics may require an altered dosing frequency to maximize bacterial killing by preserving the C_{max}/MIC .

Glycopeptides, oxazolidinones, fluoroquinolones, polymyxins, daptomycin, azithromycin, and tigecycline are examples of concentration-dependent with time-dependent antibiotics. For vancomycin, this can mean higher doses, but that comes with an increased risk of toxicity. For this reason, continuous vancomycin infusions may be considered to achieve optimal concentrations in some patients (122). For concentration-dependent with time-dependent antibiotics, dose optimization involves adjusting the dosing interval rather than administered dose (118).

13) In children with septic shock or sepsis-associated organ dysfunction who are receiving antimicrobials, we recommend daily assessment (e.g., clinical, laboratory assessment) for de-escalation of antimicrobial therapy (BPS).

Remarks: This assessment should include a review of the ongoing indication for empiric antimicrobial therapy after the first 48 hours that is guided by microbiologic results and in response to clinical improvement and/or evidence of infection resolution. This recommendation applies to patients being treated with empiric, targeted, and combination therapy.

Rationale: The misuse and overuse of broad-spectrum antimicrobials in healthcare, the community, veterinary medicine, and the environment have contributed to a global public health emergency (123). De-escalation of antimicrobials, where appropriate, is warranted to minimize adverse effects of unnecessarily prolonged administration. To date, QI efforts in adults have shown that safe and effective antimicrobial de-escalation can be achieved by daily assessment and discussion (124, 125).

Several host biomarkers have also been proposed to aid in the safe de-escalation of antimicrobial therapy. In adults with severe infections and sepsis, procalcitonin has been shown to successfully guide de-escalation (126–130) with an associated improved mortality (131). Similar reductions in length of antimicrobial therapy have also been safely achieved in neonatal populations (132) using procalcitonin as a guide. In the United Kingdom, the NICE committee concluded that in emergency department and critical care settings, procalcitonin testing shows promise, but currently, insufficient evidence is available to recommend the routine adoption of procalcitonin-guided antimicrobial de-escalation (www.nice.org.uk/guidance/dg18).

Although a relationship between antimicrobial stewardship programs (ASPs) and a decrease in antimicrobial resistance has not yet been shown, studies suggest that inpatient pediatric ASPs may reduce antimicrobial usage without contributing to adverse patient outcomes (123). The “Start Smart - Then Focus” work from Public Health England suggests a pragmatic approach of the five “antimicrobial prescribing decision” options to include 1) stop antimicrobials if there is no evidence of infection, 2) switch antimicrobials from IV to oral, 3) change antimicrobials—ideally to a narrower spectrum—or broader if required, 4) continue and document next review date or stop date, and 5) outpatient parenteral antimicrobial therapy (133). De-escalating antimicrobial therapy must be based in sound clinical judgment and needs to be adapted to local epidemiology and identified resistance patterns.

14) We recommend determining the duration of antimicrobial therapy according to the site of infection, microbial etiology, response to treatment, and ability to achieve source control (BPS).

Rationale: The main purposes of antimicrobial therapy in patients with sepsis are to reduce the pathogen load rapidly and to prevent recurrence. Important determinants of the required duration of antimicrobial therapy include site of infection, ability to drain or remove fixed infectious foci, choice of antimicrobial therapy, time to clearance of positive cultures, the nature of the causative pathogen, and the integrity of the host immune response. There is no evidence that severity of sepsis is an important determinant of optimal duration of therapy because illness severity is not expected to affect clearance of infection.

The optimal duration of antimicrobial therapy can differ by site of infection because of a high pathogen burden, poor antimicrobial penetration, or presence of difficult-to-eradicate microbial biofilms at the site. For example, longer duration of therapy is typically required for treatment of endocarditis, undrained abscesses, and prosthetic joint infection without device removal (134–136). Characteristics of the causative organism that may affect optimal duration of therapy include resistance or decreased susceptibility to front-line antimicrobials and propensity to cause deep-seated or difficult-to-eradicate infection. For example, optimal duration of treatment for endocarditis caused by methicillin-susceptible *S. aureus* may be shorter

than for that caused by MRSA (136). Similarly, although 7–10 days of therapy is appropriate for treatment of uncomplicated gram-negative bacteremia in immunocompetent hosts (137, 138), uncomplicated *S. aureus* bacteremia requires a longer course of therapy to effect cure (139–141), likely because of unrecognized seeding (142). Integrity of host immunity may also affect clearance of infection, so antimicrobial therapy for infection in neutropenic pediatric patients with cancer is often continued until resolution of neutropenia (78).

A systematic review evaluated studies describing duration of treatment for clinically and microbiologically-documented infections in children and provides evidence-based clinical guidelines for optimal duration of antimicrobial therapy for specific conditions (143). Given the lack of studies on the duration of antimicrobial therapy for pediatric patients with sepsis specifically, we refer to this previously published guideline as best evidence. Importantly, there are no data to support that the presence of organ dysfunction or a higher initial illness severity necessitates longer therapy for specific infection types (other than attention to how such organ dysfunction may affect antimicrobial pharmacokinetics and pharmacodynamics).

Observational studies suggest that longer exposure to antibiotics is associated with risk of potential adverse events including necrotizing enterocolitis in very low birthweight infants (144), candidemia in hospitalized children (145, 146), development of antimicrobial resistance (147) and *C. difficile* (formerly *Clostridium*) infection (148). Several meta-analyses, RCTs, and observational studies have compared long- versus short-duration antibiotic therapy for serious infections (140, 144, 149–167). Most studies suggest that shorter courses were associated with similar clinical outcomes compared with longer durations; these include neonatal bacteremia (158, 163), pyelonephritis (168), uncomplicated bacterial meningitis (154, 155, 159–161, 164, 165), and pneumonia (169, 170). In contrast to these infections, some studies have identified scenarios where longer durations of antimicrobial therapy is superior. For example, an RCT suggested that 14 days of antibiotic therapy was superior to 7 days for treatment of neonates with *S. aureus* bacteremia (140), and an observational study suggested that greater than 10 days was superior to less than or equal to 10 days of antibiotic therapy in children treated for gram-negative bacteremia without removal of a preexisting central venous catheter (CVC) (162).

SOURCE CONTROL

15) We recommend that emergent source control intervention be implemented as soon possible after a diagnosis of an infection amenable to a source control procedure is made (BPS).

Remarks: Appropriate diagnostic testing to identify the site of infection and microbial etiology should be performed, and advice from specialist teams (e.g., infectious diseases, surgery) should be sought, as appropriate, in order to prioritize interventions needed to achieve source control.

16) We recommend removal of intravascular access devices that are confirmed to be the source of sepsis or septic shock after other vascular access has been established and depending on the pathogen and the risks/benefits of a surgical procedure (strong recommendation, low quality of evidence).

Rationale: Source control is defined as physical modalities taken to control or remove the source of infection or to prevent spread of the infection systemically or to adjacent tissues (171). Source control may include percutaneous or deep abscess drainage, drainage of an empyema, septic joint, or subperiosteal abscess, removal of infected hardware or CVCs, or debridement of necrotizing soft-tissue infection. The adult SSC guidelines recommend source control as soon as is reasonably feasible after resuscitation, ideally within 6–12 hours of diagnosis (50). Waiting for patients to clinically stabilize prior to intervention is not recommended, as delaying adequate source control may lead to further clinical deterioration (6). Although source control as an adjunct to antimicrobial and other medical therapy has been best described for abdominal infections in adults and has been associated with reduction in mortality (172), the role of source control for pediatric sepsis has been less well elucidated (173).

The importance of source control in children has been shown for skin and deep tissue abscesses and necrotizing fasciitis (173–175). Despite the relative paucity of pediatric data, source control is an important facet of treatment of sepsis, and should not be delayed. Larger collections containing infected material often are poorly penetrated by IV antimicrobials and contribute to direct and hematogenous spread, ongoing inflammation, and organ dysfunction.

A common, but potentially preventable, source of infection is central line-associated bloodstream infections. Delayed removal of a CVC in neonates and in patients with fungemia or Enterobacteriaceae bacteremia increases the risk of death or slows recovery (176–179). Removal of a CVC that is the source of infection is therefore generally warranted unless extenuating circumstances exist. Fungal infection dictates immediate removal, while in case of coagulase-negative *Staphylococcus species* or clinically stable patients with infection caused by gram-negative bacilli, infections can often be initially treated through the CVC as a temporizing measure. The decision to remove the CVC, or not, should ultimately be made based on the pathogen suspected/recovered and host factors, such as immune status (**Supplemental Table 3**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

FLUID THERAPY

17) In healthcare systems with availability of intensive care, we suggest administering up to 40–60 mL/kg in bolus fluid (10–20 mL/kg per bolus) over the first hour, titrated to clinical markers of cardiac output and discontinued if signs of fluid overload develop, for the initial resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

18) In healthcare systems with no availability of intensive care and *in the absence of hypotension*, we recommend against bolus fluid administration while starting maintenance fluids (strong recommendation, high quality of evidence).

19) In healthcare systems with no availability of intensive care, *if hypotension is present*, we suggest administering up to 40 mL/kg in bolus fluid (10–20 mL/kg per bolus) over the first hour with titration to clinical markers of cardiac output and discontinued if signs of fluid overload develop (weak recommendation, low quality of evidence).

Remarks: Clinical markers of cardiac output may include heart rate, blood pressure, capillary refill time, level of consciousness, and urine output. In all settings, the need for fluid administration should be guided by frequent reassessment of clinical markers of cardiac output, serial blood lactate measurement and advanced monitoring, when available. Signs of fluid overload that should limit further fluid bolus therapy may include clinical signs of pulmonary edema or new or worsening hepatomegaly.

Rationale: Effective fluid resuscitation in septic shock can correct hypovolemia caused by capillary leak, vasodilation, and fluid losses. Without maintenance of adequate atrial filling pressures, cardiac output will fall and organ perfusion will be compromised.

Three RCTs of different volume resuscitation strategies in children with septic shock in settings in which advanced supportive care (e.g., intubation, mechanical ventilation, and intensive care) was accessible have been published (180–182). These studies have a combined total of only 316 children and showed no difference in mortality between the restrictive and liberal fluid resuscitation groups (**Supplemental Table 4** and **Supplemental Fig. 2**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

In geographic settings in which advanced supportive care, including mechanical ventilation, is limited and/or intensive care is not routinely accessible, the only large-scale RCT of different bolus fluid volume resuscitation strategies in severe infection in children was the Fluid Expansion as Supportive Therapy (FEAST) study (Supplemental Table 4 and Supplemental Fig. 2, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>) (183). The FEAST study was conducted in Africa in a low-resource setting without access to PICU admission. Children between 60 days and 12 years old with a severe febrile illness and abnormal perfusion were randomized to either rapid volume expansion with 20 mL/kg of IV 0.9% saline or 5% albumin or no bolus with maintenance fluid only (control group). Among the 3,141 study participants, malaria and anemia were highly prevalent. Overall, the RCT demonstrated a lower mortality after 48 hours in children receiving conservative fluid therapy (i.e., no bolus fluid, maintenance fluid only) than among those given liberal initial fluid therapy (i.e., 20 mL/kg fluid bolus with maintenance fluid) with a RR of 0.72 (95% CI, 0.57–0.9). Notably, 29 additional children enrolled with severe hypotension (systolic blood pressure of < 50 mm Hg in children younger than 12 months old,

< 60 mm Hg in children 1 to 5 years old, and < 70 mm Hg in children older than 5 years old) were treated with 40 mL/kg fluid bolus per the planned protocol without randomization to the control group. One additional child who was randomized to the control group also received a 40 mL/kg fluid bolus due to severe hypotension.

For children with septic shock diagnosed by abnormal perfusion or hypotension in healthcare systems with availability of advanced supportive and intensive care, and in the absence of signs of fluid overload, the panel suggests administering up to 40–60 mL/kg fluid bolus therapy in the first hour of resuscitation. Fluid resuscitation should be titrated to clinical markers of cardiac output and discontinued if signs of fluid overload develop. Clinical markers of cardiac output can include heart rate, capillary refill, and urine output. Although no high-quality RCTs demonstrate clear superiority of this practice, numerous observational studies have reported improved patient outcomes with routine administration of up to 40–60 mL/kg fluid bolus therapy in the first hour of resuscitation (8, 32, 33, 36, 184–187). The panel provides only a weak recommendation for this resuscitation strategy in healthcare systems with availability of intensive care because a more restrictive fluid resuscitation strategy has not been shown to be inferior in this setting and indirect data (183) indicate harm from rapid fluid boluses in other settings. For this recommendation, the panel judged the balance of observational data supporting initial fluid bolus therapy to outweigh an indirect suggestion of harm because the generalizability of the FEAST trial to healthcare systems with availability of advanced supportive and intensive care is not clear.

For children with septic shock without signs of fluid overload in low-resource settings where advanced supportive and intensive care is not available, the panel recommends against bolus fluid administration, while starting maintenance fluids, in the first hour *if hypotension is not present*, and suggests administering up to 40 mL/kg in bolus fluid (10–20 mL/kg per bolus) over the first hour *if hypotension is present*. The strong recommendation against bolus fluid if hypotension is not present was based on the FEAST trial, in which rapid bolus fluid in the first hour of resuscitation increased mortality compared with maintenance fluids only.

For the subset of children with septic shock *and hypotension*, we suggest cautious administration of fluid bolus therapy in low-resource settings because there are insufficient data to conclude that fluid resuscitation is not beneficial in children with septic shock and hypotension. In the FEAST study, all children with “severe” hypotension were treated with 40 mL/kg of bolus fluid (183), and so it is not known if fluid bolus therapy was beneficial or harmful in this subgroup of children. It should also be noted that children with gastroenteritis were excluded from FEAST, as ongoing fluid losses should be replaced with IV or oral rehydration as indicated. A recent analysis of children with “moderate” hypotension who were randomized to either fluid bolus or maintenance fluid in the FEAST trial was published after completion of our initial systematic review but considered by the panel to be potentially

influential (188). In this analysis, only children with moderate hypotension were included because children with severe hypotension were not allocated to the control (no bolus) arm. Fluid bolus therapy in children with moderate hypotension was not beneficial or harmful compared with maintenance fluid only (RR of death = 1.48; 95% CI, 0.61–3.66; $p = 0.41$). Although children who were reclassified as meeting all three World Health Organization (WHO) shock criteria of cold extremities, prolonged capillary refill greater than 3 seconds, and weak, fast pulse (14) had 48% mortality in the bolus groups versus 20% mortality in the control group, this difference was not statistically significant ($p = 0.07$). These cases were a very small proportion of the total FEAST trial participants (only 72 [2.3%] had moderate hypotension and 65 [2%] met the full WHO shock criteria), and no data were provided about differential patient characteristics between these very small post hoc subgroups to assess for potential confounding. Therefore, until further data are available, the panel suggests cautious administration of fluid bolus therapy for the subset of children with septic shock and hypotension in low-resource settings as a weak recommendation based on low quality of evidence.

Although a suggestion of “up to” 40 mL/kg was included for hypotensive shock in low-resource settings because this volume was administered to children with severe hypotension in the FEAST study, fluid administration should always be titrated to clinical markers of cardiac output and discontinued if signs of fluid overload develop. For purposes of this weak recommendation, hypotension can be defined as 1) systolic blood pressure of less than 50 mm Hg in children younger than 12 months old, less than 60 mm Hg in children 1 to 5 years old, and less than 70 mm Hg in children older than 5 years old (183) or 2) by the WHO criteria of cold extremities “with” prolonged capillary refill greater than 3 seconds and weak, fast pulse (14). Although the panel did not review different approaches to fluid bolus therapy in hypotensive children in low-resource settings, WHO recommends 10–20 mL/kg of isotonic crystalloid over 30–60 minutes, followed by an additional 10 mL/kg over 30 minutes if condition has not improved and signs of fluid overload, cardiac failure, or neurologic deterioration have not developed (14).

Fluid boluses may be administered as 10 or 20 mL/kg, according to clinician preference. To facilitate rapid IV fluid administration (as well as other IV therapies, such as antimicrobials and vasoactive medications), clinicians should consider alternative methods of vascular access if initial attempts at peripheral vein cannulation are not immediately successful. Intraosseous access is rapid and effective and recommended by Pediatric Advanced Life Support, Advanced Pediatric Life Support, and the International Liaison Committee on Resuscitation. Ultrasound-guided peripheral IV catheter placement, CVCs, and umbilical venous catheter access are alternatives if the skills are immediately available (189, 190). In all healthcare systems, repeat boluses should only be administered after reassessment of hemodynamic status if shock has not resolved and signs of fluid overload are not present.

Although fluid bolus therapy should be discontinued if signs of fluid overload are present or develop, early recognition of fluid overload by clinical examination is a challenge in children. Identifying fluid overload is especially difficult in young children, in whom crackles (rales) are often absent even in the context of gross pulmonary edema. Worsening respiratory status, particularly increasing respiratory rate, radiographic evidence of pulmonary edema in an intubated patient, or new or expanding hepatomegaly may be the only clues of evolving fluid overload. Bedside ultrasound may also be helpful to assess fluid overload, as there is emerging evidence to suggest that a “full” inferior vena cava with minimal variation across the respiratory cycle demonstrated on ultrasound indicates a fluid-replete circulation (191).

20) We suggest using crystalloids, rather than albumin, for the initial resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, moderate quality of evidence).

Remarks: Although there is no difference in outcomes, this recommendation takes into consideration cost and other barriers of administering albumin compared with crystalloids.

Rationale: The FEAST trial investigated 3,141 African children with infection and impaired perfusion, who were randomly assigned to resuscitation with 5% human albumin solution or 0.9% saline boluses or no boluses at admission to the hospital. Although both the albumin and 0.9% saline arms exhibited higher mortality than the no bolus arm, comparing human albumin solution to 0.9% saline (RR, 1.02; 95% CI, 0.8–1.28) showed no difference in mortality (183). In the absence of any clear benefit of albumin administration in children with sepsis, and in view of the additional costs in comparison to crystalloids, problems of availability, and the potential risk of blood-borne infection, we suggest against the routine use of albumin for initial fluid resuscitation in children with sepsis.

21) We suggest using balanced/buffered crystalloids, rather than 0.9% saline, for the initial resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence).

Rationale: Increasing evidence from observational studies and RCTs in adults suggests that resuscitation with crystalloid fluids containing high chloride concentrations (e.g., 0.9% saline) is associated with hyperchloremic acidosis, systemic inflammation, acute kidney injury (AKI), coagulopathy, and mortality when compared with resuscitation with more balanced/buffered crystalloids (e.g., lactated Ringer’s, Plasma-Lyte) (192). Although no pediatric RCTs compare balanced/buffered crystalloids to 0.9% saline, there are two large observational studies in children with sepsis (193, 194). They included a total of 30,532 children with sepsis, 2,100 of whom received only balanced/buffered crystalloids for the first 72 hours of hospital admission, and 28,432 who received 0.9% saline (**Supplemental Table 5**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). These studies showed that use of balanced/buffered crystalloids was associated with lower

mortality (OR, 0.79; 95% CI, 0.65–0.95) but not AKI (OR, 0.98; 95% CI, 0.94–1.02) (193, 194). Indirect evidence from adult patients, including two large RCTs, also demonstrates benefit with balanced/buffered crystalloids over 0.9% saline, with adult patients who received larger volumes of fluid and those with sepsis exhibiting the greatest benefit (192, 195). Taken together, these data support that the desirable consequences of balanced/buffered crystalloids probably outweigh the undesirable consequences (including cost), especially in those who require large volume of fluid resuscitation. Therefore, pending further high-quality pediatric data, we suggest that balanced/buffered crystalloids should generally be preferred over 0.9% saline for resuscitation of children with septic shock or other sepsis-associated organ dysfunction without a specific indication for an alternative fluid type (e.g., 0.9% saline may be preferred in patients with hyponatremia or concern for increased intracranial pressure).

22) We recommend against using starches in the acute resuscitation of children with septic shock or other sepsis-associated organ dysfunction (strong recommendation, moderate quality of evidence).

Rationale: No studies compare starches with other fluids in children. However, in adults with severe sepsis and septic shock (**Supplemental Table 6**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>), two large RCTs showed increased risk of mortality, coagulopathy, and AKI in patients receiving hydroxyethyl starch (HES) (196, 197). A meta-analysis further confirmed the risk of harm with HES (198). In the United States, the Food and Drug Administration has restricted the use of HES (199) and the European Medicines Agency has recommended complete suspension of its use (200). Therefore, we strongly recommend against the use of HES in children with sepsis.

23) We suggest against using gelatin in the resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Rationale: One RCT of gelatin-derived fluid in pediatric septic shock compared it to 0.9% saline in 60 patients. The estimates were imprecise, and showed no difference in mortality, days of using vasoactive medications, or AKI between the two groups (201) (**Supplemental Table 7**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). In the absence of any data indicating benefit of gelatin in children, we suggest against its use in pediatric sepsis.

HEMODYNAMIC MONITORING

24) We were unable to issue a recommendation about whether to target mean arterial blood pressure (MAP) at the 5th or 50th percentile for age in children with septic shock and other sepsis-associated organ dysfunction. However, in our practice, we target MAP to between the 5th and 50th percentile or greater than 50th percentile for age.

Rationale: Although no data from RCTs support specific hemodynamic targets in children, evidence suggests that targeting MAP of approximately 65 mm Hg (5th percentile) in adults with septic shock may be beneficial (202). In the absence of evidence from RCTs, we were unable to reach consensus to recommend a specific MAP target for children. However, in our practice, 37% of panel members reported targeting MAP between the 5th and 50th percentile for age and 45% reported targeting MAP greater than 50th percentile for age. Many panelists also commented that lower blood pressures are acceptable if other hemodynamic variables (e.g., mental status, perfusion, urine output, lactate) are improving. RCTs to define optimal hemodynamic targets, including MAP, are urgently required to inform practice in pediatric sepsis. In settings where direct measurement of MAP is less reliable, systolic blood pressure provides a reasonable alternative.

A previous recommendation to target perfusion pressure (MAP minus central venous pressure [CVP]) lacks supporting data (203). Prioritizing CVP measurement is also impractical during early resuscitation (such as in most pediatric emergency departments); CVP also provides an unreliable assessment of left ventricular preload.

- 25) We suggest not using bedside clinical signs in isolation to categorize septic shock in children as “warm” or “cold” (weak recommendation, very low quality of evidence).
- 26) We suggest using advanced hemodynamic variables, when available, in addition to bedside clinical variables to guide the resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Remarks: Advanced hemodynamic monitoring may include cardiac output/cardiac index, systemic vascular resistance, or central venous oxygen saturation (ScvO₂).

Rationale: The ACCM previously recommended clinical assessment of children in septic shock to differentiate “warm” versus “cold” shock based on extremity temperature, capillary refill, pulse strength, diastolic blood pressure, and pulse pressure. Depending on “warm” or “cold” classification, different resuscitation strategies were suggested (e.g., fluid and vasopressors for “warm” shock and inotropes for “cold” shock). However, a number of observational studies have demonstrated very poor correlation of clinical assessments with cardiac index and systemic vascular resistance as measured by advanced monitoring (204–209). Indeed, many children who appeared to have “warm” shock by clinical examination had evidence of myocardial dysfunction, thus demonstrating the challenge of using clinical signs alone to direct therapy. Hence, we suggest not attempting to make this distinction using clinical assessments alone, although this categorical distinction may be helpful if advanced hemodynamic monitoring is available to assess patient physiology more accurately. Examples of advanced monitoring include invasive arterial blood pressure monitoring with pulse contour analysis, ultrasound Doppler of the ascending or descending thoracic aorta (suprasternal or esophageal Doppler), cardiac ultrasound/echocardiography

(210), or measurement of ScvO₂ (190). All of these variables (other than ScvO₂) will provide additional assessment of cardiac index and/or systemic vascular resistance index beyond clinical signs, which may then be used to direct and titrate treatment. There is also emerging evidence that fluid responsiveness may be predicted by aortic blood flow peak velocity variation in mechanically ventilated children (211). In an RCT of 90 children admitted to a PICU in Egypt, addition of serial echocardiography provided early recognition of septic myocardial dysfunction and hypovolemia that was not apparent on clinical assessment and resulted in faster shock reversal, less fluid overload, shorter LOS, and lower mortality compared with the group without serial echocardiography (210). When advanced hemodynamic monitoring is available, it is appropriate to target the normal range for variables such as cardiac index, systemic vascular resistance index, stroke index, and ScvO₂ (Table 5). No evidence supports targeting a supranormal range of cardiac index.

Until recently, adult guidelines have recommended early goal-directed therapy (EGDT) based on the protocol published by Rivers et al (212). This recommendation described the use of a series of “goals” that included CVP and ScvO₂. This approach is no longer recommended following a failure to show reduction in mortality in three subsequent large multicenter RCTs (213–215). In children, there has only been one small RCT supporting the use of a protocolized approach including targeting ScvO₂ greater than 70%. This study included 102 children with fluid-refractory septic shock (RSS) and showed a reduced risk of death (RR, 0.3; 95% CI, 0.13–0.68) from a very high baseline mortality of 39% (26). No high-quality RCTs have investigated other hemodynamic variables to guide therapy in children (Supplemental Table 8 and Supplemental Fig. 3, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

- 27) We suggest using trends in blood lactate levels, in addition to clinical assessment, to guide resuscitation of children with septic shock and other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence).

Remarks: In children with an elevated blood lactate, repeat testing that reveals a persistent elevation in blood lactate may indicate incomplete hemodynamic resuscitation and should prompt efforts, as needed, to further promote hemodynamic stability.

Rationale: Although blood lactate is not a direct measure of tissue perfusion, increased lactate is associated with worse outcomes in children (11). Only one pediatric observational study of lactate-guided resuscitation, which included 77 children with sepsis in the ED, was available (Supplemental Table 9, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). This study showed that lactate normalization was associated with a decreased risk of persistent organ dysfunction (RR, 0.46; 95% CI, 0.29–0.73 and adjusted RR, 0.47; 95% CI, 0.29–0.78) (56). There is also indirect evidence from adult sepsis, with six RCTs (total of 1,007 patients) evaluating lactate-guided resuscitation of patients with septic shock (216–221). The pooled estimates across all

RCTs showed significant reduction in mortality compared with resuscitation without lactate monitoring (RR, 0.66; 95% CI, 0.55–0.81) (Supplemental Table 9, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Therefore, although there was not sufficient evidence to propose a recommendation to measure lactate to differentiate low- versus high-risk of sepsis among children with infection or suspected infection (see Recommendation 2), we do suggest that blood lactate levels be used to help guide resuscitation of children with established septic shock or other sepsis-associated organ dysfunction.

VASOACTIVE MEDICATIONS

- 28) We suggest using epinephrine, rather than dopamine, in children with septic shock (weak recommendation, low quality of evidence).
- 29) We suggest using norepinephrine, rather than dopamine, in children with septic shock (weak recommendation, very low quality of evidence).
- 30) We were unable to issue a recommendation for a specific first-line vasoactive infusion for children with septic shock. However, in our practice, we select either epinephrine or norepinephrine as the first-line vasoactive infusion guided by clinician preference, individual patient physiology, and local system factors.
- 31) We were unable to issue a recommendation about initiating vasoactive agents through peripheral access in children with septic shock. However, in our practice, we often or sometimes administer a dilute concentration of the initial vasoactive medication through a peripheral vein if central venous access is not readily accessible.

Remarks: It is reasonable to begin vasoactive infusions after 40–60 mL/kg of fluid resuscitation if the patient continues to have evidence of abnormal perfusion, or sooner if fluid overload develops or other concerns for fluid administration are present. Either epinephrine or norepinephrine may be administered through a peripheral vein (or intraosseous, if in place) if central venous access is not readily accessible. Dopamine may be substituted as the first-line vasoactive infusion, administered either peripherally or centrally, if epinephrine or norepinephrine is not readily available.

Rationale: Epinephrine and norepinephrine both have vasopressor and inotropic effects, are widely used, and are effective in treating children with fluid-RSS. No studies directly compare epinephrine with norepinephrine. However, epinephrine has

been compared with dopamine in two RCTs in children with fluid-RSS (222, 223). Across both studies, epinephrine was associated with a lower risk of mortality (RR, 0.63; 95% CI, 0.40–0.99) and more organ failure-free days among survivors by day 28 (MD 4 more days; 95% CI, 2.0–6.0) (Supplemental Table 10 and Supplemental Fig. 4, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Norepinephrine has not been studied in children with septic shock, but in a randomized trial of norepinephrine versus saline in sedated, mechanically ventilated children, mortality was not different between groups (RR, 0.50; 95% CI, 0.10–2.43; Supplemental Table 11a, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>) but the norepinephrine group showed higher urine output ($p = 0.016$) and improved blood pressure ($p = 0.04$) suggesting improved perfusion relative to saline (224). Evidence from adult trials (Supplemental Table 11b, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>) shows a lower mortality rate (RR, 0.93; 95% CI, 0.86–1.00) and lower incidence of arrhythmias (RR, 0.48; 95% CI, 0.40–0.58) with norepinephrine than with dopamine, and no difference in mortality with epinephrine than with norepinephrine (RR, 0.96; 95% CI, 0.77–1.21) (225).

Evidence is insufficient to recommend either epinephrine or norepinephrine as the initial vasoactive agent for children with fluid-RSS. In a survey of our panel members, an equal number used epinephrine and norepinephrine as the first-line vasoactive medication with a general preference for epinephrine to treat myocardial dysfunction and low cardiac output and for norepinephrine to increase systemic vascular resistance. It therefore seems reasonable to use either epinephrine or norepinephrine as the initial vasoactive agent, with the choice made based on individual patient physiology, clinician preference, and local system factors. Once cardiac ultrasound/echocardiography or other advanced monitoring is available, selection of vasoactive therapy should be driven by individual patient physiology.

No pediatric data identify when shock becomes “fluid-refractory” and, thus, to guide when to start vasoactive infusions. However, excessive fluid resuscitation can lead to fluid overload, which has been associated with increased mortality in critically ill children (226). A trial comparing a fluid-sparing strategy with early initiation of vasoactive medications compared to a fluid-liberal resuscitation strategy is currently ongoing (SQUEEZE trial, [ClinicalTrials.gov NCT03080038](http://ClinicalTrials.gov/NCT03080038)). Until further data are available, we consider it reasonable to begin

TABLE 5. Normal Ranges for Advanced Monitoring

Variable	Formula	Normal Range	Units
CI	CI = cardiac output/body surface area	3.5–5.5	L/min/m ²
SI	SI = CI/heart rate	30–60	mL/m ²
SVRI	SVRI = 80 × (mean arterial pressure–central venous pressure)/CI	800–1600	dyne-s/cm ⁵ /m ²

CI = cardiac index, SI = stroke index, SVRI = systemic vascular resistance index.

vasoactive infusions after 40–60 mL/kg of fluid resuscitation if the patient continues to have evidence of abnormal perfusion. Additional fluid resuscitation may be concurrently administered if the patient demonstrates physiologic improvement following each fluid bolus and without signs of fluid overload.

All vasoactive agents, including norepinephrine, may be initiated through peripheral venous (or intraosseous, if in place) access if central venous access is not readily available to avoid delays in therapy (227, 228). However, central venous access should be obtained as soon as reasonably practicable. In our practice, 82% of panel members reported at least sometimes administering the initial vasoactive infusion peripherally if central venous or intraosseous access was not readily available, particularly in the emergency department or other non-PICU settings. Most panelists preferred epinephrine or dopamine to norepinephrine if peripheral infusion was needed. Although epinephrine or norepinephrine is the preferred first-line medication, dopamine may be substituted as the first-line vasoactive infusion, administered either peripherally or centrally, if neither epinephrine nor norepinephrine is readily available.

32) We suggest either adding vasopressin or further titrating catecholamines in children with septic shock who require high-dose catecholamines (weak recommendation, low quality of evidence).

Remarks: No consensus was achieved on the optimal threshold for initiating vasopressin. Therefore, this decision should be made according to individual clinician preference.

Rationale: Vasopressin-receptor agonists (vasopressin or terlipressin) have been studied in three RCTs in children (Supplemental Table 12, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Vasopressin was compared with saline in one study in children with vasodilatory shock (229) and in one study of children with severe lung disease (230). Terlipressin was compared with usual care in children with septic shock (231). The mortality rate (RR, 1.14; 95% CI, 0.80–1.62) and ischemic events (RR, 1.56; 95% CI, 0.41–5.91) were higher with vasopressin/terlipressin. There were fewer vasoactive-free days with vasopressin (median 25.2 d in vasopressin [interquartile range (IQR) 0.0–28.3], median 27.5 d in control [IQR, 23.1–28.9]). In six RCTs in adults, renal replacement therapy was required less often with vasopressin (RR, 0.74; 95% CI, 0.51–1.08) (232). Weighing the benefit of avoiding renal replacement therapy against the potential harm from ischemic events and the nonsignificant difference in mortality, we suggest that vasopressin may be added or catecholamines may be further titrated in children on high doses of catecholamines.

33) We were unable to issue a recommendation about adding an inodilator in children with septic shock and cardiac dysfunction despite other vasoactive agents. However, in our practice, we sometimes use inodilators in children with septic shock and evidence of persistent hypoperfusion and cardiac dysfunction despite other vasoactive agents.

Rationale: There are no RCTs of inodilators (including milrinone, dobutamine, or levosimendan) in children with

septic shock with persistent hypoperfusion and cardiac dysfunction. A report of two children described improvement in cardiac output with addition of inodilators (233). A case series of 10 children with meningococcal septic shock treated with milrinone described improved core-to-peripheral temperature gradient, with stable blood pressure and no change in acidosis (234). These data were not sufficient to formulate a recommendation. However, in our practice, 77% of panel members reported at least sometimes using inodilators in children with septic shock who had evidence of persistent hypoperfusion and cardiac dysfunction despite other vasoactive agents, typically in a PICU with advanced hemodynamic monitoring available.

VENTILATION

34) We were unable to issue a recommendation about whether to intubate children with fluid-refractory, catecholamine-resistant septic shock. However, in our practice, we commonly intubate children with fluid-refractory, catecholamine-resistant septic shock without respiratory failure.

Rationale: There are no RCTs and/or observational studies of children receiving early intubation for refractory shock without respiratory failure compared with delayed or no intubation for the same condition, nor is there suitable indirect evidence to substantiate a formal recommendation. However, it is well understood that a high metabolic demand from refractory shock typically indicated by progressive lactic acidemia and end-organ dysfunction can be, at least in part, mitigated by early invasive mechanical ventilation even without clinical symptoms of acute pulmonary edema or respiratory failure (235–237). Furthermore, chest radiograph findings can “lag” behind clinical deterioration (238, 239) such that patients with refractory shock and a “negative” chest radiograph may still progress toward more overt ARDS. Lung ultrasound may provide an alternative tool to chest radiograph in detecting lung pathology, but its utility to identify which sepsis patients may benefit from early mechanical ventilation is not yet clear (240–243). For these reasons, 48% of panel members often or always and 35% sometimes intubate children with fluid-refractory, catecholamine-resistant septic shock even in the absence of clear respiratory failure, while 17% rarely or never do so. Of note, when intubating, caution should be exercised to avoid worsening hypotension or precipitating cardiac arrest as medications used for inducing anesthesia at the time of tracheal intubation, along with conversion from spontaneous breathing to use of positive pressure ventilation, may result in a transient deterioration in patient hemodynamics. The panel does recognize that in some settings, invasive mechanical ventilation may not be available or feasible—or may even be detrimental. In these instances, transport of the patient to a higher level of care can be life-saving.

35) We suggest not to use etomidate when intubating children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Rationale: Etomidate is a short-acting IV anesthetic agent that has been used for inducing anesthesia and sedation for tracheal intubation in patients with unstable hemodynamics. However, concerns regarding the drug's effect on adrenal function have been raised in adult studies. No RCTs exist in critically ill children with or without sepsis comparing etomidate to another anesthesia/sedative regimen. Two observational studies included children. One study from 1984 (244) enrolled acutely injured adults and children (44 intubated with etomidate vs 90 intubated with a benzodiazepine and opioid). A more recent study (245) enrolled children with meningococcal sepsis or septic shock with 23 intubated with etomidate as compared with 37 intubated with any other combination of sedatives. Although caution must be taken given the small sample size, each of these studies reported higher mortality after use of etomidate (pooled OR, 4.51; 95% CI, 1.82–11.16) (**Supplemental Table 13**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). In addition, den Brinker et al (245) reported a significant association of etomidate with adrenal insufficiency, with cortisol to adrenocorticotropin hormone (ACTH) ratios decreasing by 83% after etomidate exposure. Indirect evidence is available from four RCTs in adults (246–249). In the largest of these trials, Jabre et al (249) compared 234 critically ill adults intubated with etomidate to 235 intubated with an alternative medication regimen and found higher adrenal insufficiency in the etomidate group (OR, 1.79; 95% CI, 1.37–2.36). Pooled odds of all four adult studies was 1.89 (95% CI, 1.47–2.44) with all studies suggesting significantly increased risk of adrenal insufficiency after etomidate administration. Importantly, this effect was seen even after one dose of etomidate. Unfortunately, there is no conclusive evidence to recommend an optimal alternative induction agent to etomidate, although ketamine and fentanyl are routinely available and can offer favorable hemodynamic profiles in the setting of shock.

36) We suggest a trial of noninvasive mechanical ventilation (over invasive mechanical ventilation) in children with sepsis-induced pediatric ARDS (PARDS) without a clear indication for intubation and who are responding to initial resuscitation (weak recommendation, very low quality of evidence).

Remarks: When noninvasive mechanical ventilation is initiated, clinicians should carefully and frequently reevaluate the patient's condition.

Rationale: Noninvasive mechanical ventilation with continuous positive airway pressure ventilation or bi-level positive airway pressure ventilation may allow for decreased work of breathing and improved oxygenation in the face of sepsis-induced PARDS. Therefore, it is possible to avoid intubation in sepsis patients who are identified early with mild PARDS physiology and no evidence of advancing end-organ dysfunction. However, no RCTs in either critically ill children or children with sepsis-induced PARDS compare the effect of noninvasive ventilation to invasive mechanical ventilation on clinical outcomes. Observational studies have tested whether noninvasive mechanical ventilation could mitigate the need for invasive

mechanical ventilation but none specifically focused on children with sepsis (250–256). We undertook a meta-analysis of three observational studies that evaluated the association of noninvasive mechanical ventilation with mortality in a general PICU population (252, 254, 257). Using unadjusted estimates pooled from the data across all three studies, we found noninvasive ventilation to be associated with a decreased risk of death (RR, 0.21; 95% CI, 0.09–0.47) (**Supplemental Fig. 5**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). One additional RCT in immunocompromised children with acute respiratory dysfunction did not find that early noninvasive ventilation reduced intubation compared with standard care, but the trial was small (42 participants) due to low consent and overall slow recruitment and the direct relevance to children with sepsis-induced PARDS without a clear indication for intubation and who are responding to initial resuscitation was not clear (258). Thus, it is reasonable to try noninvasive mechanical ventilation in children with sepsis-induced PARDS who do not have a clear indication for intubation. However, noninvasive ventilation should be reserved for children with sepsis who are responding to initial resuscitation, do not have evidence for ongoing or worsening end-organ dysfunction, and in whom close monitoring and frequent reevaluation can be ensured (253, 255, 259). This recommendation for children with sepsis-induced PARDS aligns with the 2015 PALICC (260) and 2017 Pediatric Mechanical Ventilation Consensus Conference (PEMVECC) (261) guidelines.

37) We suggest using high positive end-expiratory pressure (PEEP) in children with sepsis-induced PARDS (weak recommendation, very low quality of evidence).

Remarks: The exact level of high PEEP has not been tested or determined in PARDS patients. Some RCTs and observational studies in PARDS have used and advocated for use of the ARDS-network PEEP to F_{IO_2} grid though adverse hemodynamic effects of high PEEP may be more prominent in children with septic shock.

Rationale: PEEP helps to prevent alveolar collapse, restore end-expiratory lung volume, and improve mean airway pressures, all of which help to improve adequate oxygenation in PARDS patients and minimize unnecessary use of high F_{IO_2} . Adult ARDS patients have been successfully managed with judicious and strict application of a PEEP/ F_{IO_2} grid, initially implemented in an ARDS-network trial (262). This grid has been applied in children with PARDS enrolled in RCTs (263), but a pediatric-specific PEEP/ F_{IO_2} grid has not been determined or validated. In 2017, a multicenter observational study by the Collaborative Pediatric Critical Care Research Network reported that pediatric critical care clinicians almost uniformly limit PEEP to 10 cm H_2O irrespective of oxygenation and F_{IO_2} (264). This is in contrast to the PEMVECC (261) and PALICC (24) recommendations for use of PEEP in excess of 15 cm H_2O for severe PARDS patients. Our panel reviewed several observational studies of PARDS patients, all published since 2007, each including 12–30% sepsis-induced PARDS (264–276). The largest, a multicenter study by Khemani et al (276), evaluated

1,134 PARDS patients of whom 26% were managed with lower PEEP relative to ARDS Network (ARDSnet) protocol and experienced greater mortality than those managed in accordance with a higher PEEP strategy as recommended by the ARDSnet PEEP/FiO₂ grid (**Supplemental Table 14**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). After adjustment for relevant comorbidities, pediatric patients managed with a PEEP strategy at or above that recommended by the ARDSnet low PEEP/FiO₂ grid had a decreased odds of death compared with children managed with PEEP lower than that recommended by the ARDSnet low PEEP/FiO₂ grid (adjusted OR, 0.50; 95% CI, 0.31–0.81).

The panel concluded that PEEP levels greater than 10 cm H₂O may be necessary with progressive hypoxemia, with the precise amount of “high” PEEP carefully titrated for each individual while attending to the potential adverse hemodynamic effects of increasing intrathoracic pressure in children with septic shock. Therefore, although the optimal approach to setting PEEP has not yet been determined in children with PARDS, carefully increasing PEEP for children with sepsis-induced PARDS who require FiO₂ exceeding 60% and/or exhibit ongoing hypoxemia is reasonable, rather than continuing to manage such children with a low-PEEP or moderate-PEEP strategy of less than or equal to 10 cm H₂O.

38) We cannot suggest for or against the use of recruitment maneuvers in children with sepsis-induced PARDS and refractory hypoxemia.

Remarks: If a recruitment maneuver is considered, the use of a stepwise, incremental and decremental PEEP titration maneuver is preferred over sustained inflation techniques that have not been optimized through direct testing in PARDS patients. All PARDS patients must be carefully monitored for tolerance of the maneuver.

Rationale: ARDS is characterized by decreased lung compliance, risk for atelectasis, and increased intrapulmonary shunt. Recruitment maneuvers have been used in both children and adults temporarily to increase transpulmonary pressure to recruit lung units with the goal of improving both oxygenation and ventilation. Most recruitment maneuvers include either sustained inflation or a step-wise incremental or decremental PEEP titration methodology. However, many clinicians and researchers remain concerned that the optimal strategy for lung recruitment has not been determined and injudicious implementation of recruitment maneuvers can result in hemodynamic compromise (277), hypercarbia (278), and/or ventilator-induced lung injury (279). PEMVECC did not recommend use of recruitment maneuvers in children, citing an overall lack of evidence in this area (261). In contrast, the 2015 PALICC provided a weak recommendation in favor of recruitment maneuvers with prioritization of a slow stepwise incremental and decremental PEEP method (24).

Two observational studies are potentially informative about use of recruitment maneuvers in children with sepsis-induced PARDS (267, 268). (**Supplemental Table 15**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>) First,

Boriosi et al (280) enrolled 21 children with lung injury, of whom 66% had sepsis, and used incremental PEEP recruitment maneuvers. Patients experienced improved oxygenation as measured by both the PaO₂ to FiO₂ (P/F) ratio and alveolar-to-arterial oxygen gradient for the 4 hours after recruitment. Second, Duff et al (281) enrolled 32 children and used the sustained inflation technique, which also resulted in improved oxygenation for the ensuing 6 hours. However, neither study tested the association of recruitment maneuvers with clinical outcomes, such as ventilator days or mortality. Consequently, despite the potential for benefit for some patients coupled with the possibility of harm (282, 283), insufficient data do not allow us to recommend either for or against recruitment maneuvers in sepsis-induced PARDS patients at this time.

39) We suggest a trial of prone positioning in children with sepsis and severe PARDS (weak recommendation, low quality of evidence).

Remarks: Research trials in adults with ARDS and children with PARDS have emphasized prone positioning for at least 12 hours per day, as tolerated.

Rationale: Prone positioning almost uniformly improves oxygenation in adults with ARDS and children with PARDS. Although the exact mechanisms continue to be elucidated, prone position has been shown to recruit areas of collapsed, de-recruited lung with resultant improved elastance, decreased lung stress and strain, and improved functional residual capacity (284). Given that pulmonary perfusion is thought to be consistent both dorsally and ventrally, an improvement in lung aeration can be met with continued perfusion, thereby reducing ventilation-perfusion mismatching (285). Most recent RCTs in adults support use of prone positioning as a potentially life-saving management strategy (**Supplemental Table 16**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>), especially in those meeting severe ARDS criteria (i.e., P/F < 150 mm Hg) (286). This benefit is seen particularly in patients who are positioned for prolonged periods of time, most commonly reported as 12–20 hours per day. Two pediatric RCTs tested the use of prone positioning in PARDS patients (263, 287). Pooled analyses of these two studies yielded a RR of 0.99 (95% CI, 0.36–2.69) for mortality in prone positioning as compared with supine positioning for this patient population (**Supplemental Table 16** and **Supplemental Fig. 6**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Importantly, no serious adverse events were reported in these trials, although the prone positioning methodology was protocolized in each with particular attention to avoid accidental endotracheal extubation and pressure injury. PALICC (24) did not recommend routine use of prone positioning in PARDS patients but suggested its consideration in severe PARDS. The panel noted that the National Institutes of Health has approved and funded an international RCT of prone positioning in severe PARDS (ClinicalTrials.gov identifier NCT02902055).

40) We recommend against the routine use of inhaled nitric oxide (iNO) in all children with sepsis-induced PARDS (strong recommendation, low quality of evidence).

41) We suggest using iNO as a rescue therapy in children with sepsis-induced PARDS and refractory hypoxemia after other oxygenation strategies have been optimized (weak recommendation, moderate quality of evidence).

Rationale: The presumptive mechanism of sepsis-induced PARDS involves alveolar epithelial injury, vascular endothelial injury, and activation of inflammatory, fibrosis, and coagulation cascades. As such, PARDS is not a disease process primarily of pulmonary arterial hypertension, the therapeutic target of iNO therapy, and so is not recommended for routine use in children with sepsis-associated PARDS. Nonetheless, many PARDS patients have comorbidities that include risk for pulmonary hypertension (e.g., chronic lung disease after prematurity, congenital heart disease after repair or palliation) or clinical features, such as acidemia and hypoxemia that increase pulmonary arterial pressures. Thus, iNO therapy may be considered in children with documented pulmonary hypertension or severe right ventricular dysfunction (239, 288). Such use of iNO in sepsis must be balanced against its lack of availability or high cost in many areas of the world and, that once in place, iNO use carries a potential patient safety consideration as inadvertent and abrupt discontinuation of the therapy can result in a rapid and potentially life-threatening rebound pulmonary hypertensive crisis.

Several small RCTs (289–291) and observational studies have described significant improvement in oxygenation after iNO therapy (292). Many, but not all, of these studies include patients with sepsis (290, 291, 293–296), and few analyze longer term, clinically relevant outcomes such as mortality. A 2016 Cochrane review indicated no mortality benefit from iNO administration (RR, 0.78; 95% CI, 0.51–1.18) in three RCTs (297). Our analysis of two recent observational studies, one conducted in children on ECMO and another in children with severe PARDS, respectively, suggest possible increased mortality risk (294, 296), whereas one RCT of 55 PARDS patients indicated improved duration of mechanical ventilation in PARDS survivors (291) (**Supplemental Table 17** and **Supplemental Fig. 7**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Taken together, these data do not support “routine” use of iNO in all children with sepsis-induced PARDS but do raise the potential for benefit as an emergency rescue therapy for severe, sepsis-induced PARDS with refractory hypoxemia after other oxygenation strategies have been optimized. Emergency rescue use of iNO may allow time to realize benefit from other therapies, such as lung recruitment, or provide a bridge to ECMO or another intervention. However, when iNO is used, we agree with the PALICC recommendation that “assessment of benefit must be undertaken promptly and serially to minimize toxicity and to eliminate continued use without established effect” (24). These recommendations align with the 2004 guidelines for use of iNO therapy in neonates and children issued by the European Society for Pediatric and Neonatal Intensive Care (288), PALICC guidelines (24), and a 2017 Cochrane review (292) as no relevant change in evidence has become available.

42) We were unable to issue a recommendation to use high-frequency oscillatory ventilation (HFOV) versus conventional ventilation in children with sepsis-induced PARDS. However, in our practice, there is no preference to use or not use HFOV in patients with severe PARDS and refractory hypoxia.

Rationale: HFOV provides a sustained mean airway pressure with superimposed high frequency, pendelluft-type, oscillatory breaths that may improve oxygenation in patients with moderate-to-severe lung disease while minimizing barotrauma, volutrauma, and atelectrauma. However, the most efficacious timing of application, optimal settings, and ideal population of patients likely to benefit have not been well established. HFOV may be difficult to apply effectively in centers with little experience and is not universally available. Despite these practical limitations, both PALICC (24) and PEMVECC (261) endorsed cautionary use of HFOV as an alternative type therapy in patients with severe PARDS. In our panel, clinicians who use versus those who do not use HFOV in patients with severe PARDS and refractory hypoxia were nearly evenly distributed.

Application of HFOV in adult ARDS patients has yielded concerning results due to a potentially increased mortality observed in the adult OSCILLATE RCT (298) and a neutral result in the adult OSCAR RCT (299). Pediatric data include two observational studies with a non-HFOV control group and three randomized trials. In the two observational studies, oxygenation improved with HFOV relative to conventional ventilation but there was a nonsignificant trend toward increased mortality (Guo et al [300]: 34.6% vs 22.7%; adjusted OR, 2.74; 95% CI, 0.52–14.6 and Bateman et al [301]: 25% vs 17%; adjusted OR, 1.28; 95% CI, 0.92–1.79). Among three small RCTs, however, a trend toward reduced mortality in those managed with HFOV was observed (pooled RR, 0.77; 95% CI, 0.43–1.36) (302–304). A large, multicenter, international RCT of HFOV compared with conventional mechanical ventilation in severe PARDS patients, including children with and without sepsis, is underway and will seek to address many of these issues (www.clinicaltrials.gov/NCT02902055).

43) We suggest using neuromuscular blockade in children with sepsis and severe PARDS (weak recommendation, very low quality of evidence).

Remarks: The exact duration of neuromuscular blockade to use in severe PARDS patients has not been determined to date. Most of the adult RCT data and pediatric observational data support treatment for 24–48 hours after ARDS onset.

Rationale: Indirect evidence from three adult RCTs (305–307) found that early use of neuromuscular blocking agents (NMBAs) for up to 48 hours in adults with severe ARDS, defined as P/F ratio less than 150 mm Hg, improved 90-day survival and shortened duration of mechanical ventilation without increasing muscle weakness. In a multi-center double-blind RCT (307), 340 patients with early severe ARDS, meeting criteria within 48 hours, were randomized to receive either cisatracurium besylate

or placebo once adequately sedated. After adjustment for baseline P/F, plateau pressure, and the Simplified Acute Physiology Score, the cisatracurium group had a hazard ratio for death at 90 days of 0.68 (95% CI, 0.48–0.98) compared with the placebo group. Early use of NMBAs was also associated with decreased organ system dysfunction, less air leak, and a decreased pro-inflammatory response (308). These findings remained consistent when combined with earlier smaller studies from the same group of investigators in a meta-analysis. However, the more recent ROSE trial of early neuromuscular blockade in adults with moderate to severe ARDS was stopped futility at the second interim analysis (enrollment of 1,006 patients) with a 90-day mortality difference of 42.5% in the intervention group versus 42.8% in the control group. In this study, the intervention group received continuous cisatracurium and deep sedation for 48 hours compared with the control group that received lighter sedation targets (Richmond Agitation Scale of 0 to –1). Both groups received low tidal volume ventilation with high PEEP strategy. Notably, only 13.8% of patients enrolled in ROSE had nonpulmonary sepsis as a primary diagnosis.

In pediatrics, there are no prospective data regarding the use of NMBAs in PARDS (with or without sepsis), although there is an ongoing pediatric trial in the Netherlands (ClinicalTrials.gov NCT02902055). In one large retrospective study of 317 children with PARDS, of whom 23% experienced sepsis-induced PARDS (309), mortality was lower in those children treated with neuromuscular blockade (8.8% vs 17.7%). However, duration of mechanical ventilation was longer in the treatment group and proportion with neuromuscular weakness was not assessed (**Supplemental Table 18**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

CORTICOSTEROIDS

- 44) We suggest against using IV hydrocortisone to treat children with septic shock if fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability (weak recommendation, low quality of evidence).
- 45) We suggest that either IV hydrocortisone or no hydrocortisone may be used if adequate fluid resuscitation and vasopressor therapy are not able to restore hemodynamic stability (weak recommendation, low quality of evidence).

Rationale: A potential role for IV hydrocortisone as adjunctive therapy for septic shock is supported by various roles of cortisol in homeostasis and the stress response. For example, cortisol directly decreases reuptake of norepinephrine (310), and enhances calcium availability in myocardial and vascular smooth muscle cells (311) promoting myocardial contractility and vasoconstriction, respectively. Cortisol helps to inhibit prostacyclin and endogenous nitric oxide production, resulting in increased vascular tone (312), modulation of capillary leak (313), and augmentation of the beta-adrenergic receptor in the heart (312). However, potential adverse side effects of corticosteroid therapy include hyperglycemia (314, 315), catabolism-related diffuse neuromuscular weakness (including the diaphragm) (316, 317), and hospital-acquired infections (318).

These effects may be under-appreciated in critically ill patients but can contribute to worse outcomes (319).

At least one pediatric (320) and several adult (321) interventional trials examining adjunctive corticosteroids for septic shock have concluded that this drug class hastens resolution of shock. Of the four adult high-quality contemporary RCTs, two reported a mortality reduction and two did not (322–326). A recent meta-analysis of 42 RCTs including 9,969 adults and 225 children with sepsis found that corticosteroids possibly result in a small reduction in short-term mortality (RR, 0.93; 95% CI, 0.84–1.03), long-term mortality (0.94; 95% CI, 0.89–1.00), faster resolution of shock, and shorter LOS, while also possibly increasing the risk of neuromuscular weakness (RR, 1.21; 95% CI, 1.01–1.52) (327). Despite a weak recommendation to treat sepsis with hydrocortisone based on the findings noted in the overall meta-analysis (328), the pediatric studies enrolled a combined small number of subjects, reported inconsistent conclusions, had methodologic limitations, and did not demonstrate an overall mortality reduction (320, 329–331) (**Supplemental Table 19**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

Observational cohort studies have reported either harm or no benefit with hydrocortisone in children with septic shock (5, 332–336). For example, a retrospective analysis of the REsearching severe Sepsis and Organ dysfunction in children: a gLocal perspective trial of activated protein C in pediatric sepsis found no differences in mortality, duration of mechanical ventilation and vasoactive-inotropic support, or PICU stay among 193 children who received and 284 who did not receive open-labeled corticosteroids (333). Despite the post hoc analysis, age, sex, Pediatric Risk of Mortality (PRISM) III scores, baseline number of dysfunctional organs, and baseline Pediatric Overall Performance Category scores did not differ between corticosteroid-treated and corticosteroid nontreated groups.

Several pediatric and adult studies have attempted to use random cortisol and/or cosyntropin-stimulated cortisol serum concentrations to identify which patients with septic shock may benefit from hydrocortisone therapy, but reliable cutoffs have not been clearly identified. Challenges relate to variability in 1) the cortisol assay itself; 2) cortisol metabolism (11-beta-hydroxysteroid dehydrogenase) during sepsis; 3) corticosteroid-binding globulin concentrations; and 4) multiple tissue (e.g., elastase, anti-glucocorticoid compounds) and cellular (e.g., glucocorticoid receptor) factors. Therefore, use of random cortisol or stimulation tests to guide corticosteroid prescription in children with septic shock cannot be recommended as this time. However, for any patient with a clinical concern for primary adrenal insufficiency (e.g., a patient with significant and unexplained hypoglycemia, hyponatremia, and/or hyperkalemia), a high-dose cosyntropin-stimulation test should be performed. Interpretation should focus on the baseline serum ACTH concentration (above normal indicating primary adrenal insufficiency) and the 60-minute stimulated serum cortisol concentration (< 18 µg/dL indicating primary adrenal insufficiency) (337).

In summary, no high-quality investigations currently support or refute the routine use of adjunctive corticosteroids for pediatric septic shock or other sepsis-associated organ dysfunction. At the time of this publication, an RCT is in progress to examine the potential risks and benefits of adjunctive hydrocortisone for fluid and vasoactive-inotropic recalcitrant septic shock in children. However, this uncertainty does not apply to children presenting with septic shock or other sepsis-associated organ dysfunction who also have acute or chronic corticosteroid exposure, hypothalamic-pituitary-adrenal axis disorders, congenital adrenal hyperplasia or other corticosteroid-related endocrinopathies, or have recently been treated with ketoconazole or etomidate, for whom prescription of stress-dose hydrocortisone is indicated, with or without evaluation of the adrenal axis (338).

ENDOCRINE AND METABOLIC

- 46) We recommend against insulin therapy to maintain a blood glucose target at or below 140 mg/dL (7.8 mmol/L) (strong recommendation, moderate quality of evidence).
- 47) We were unable to issue a recommendation regarding what blood glucose range to target for children with septic shock or other sepsis-associated organ dysfunction. However, in our practice, there was consensus to target blood glucose levels below 180 mg/dL (10 mmol/L) but there was not consensus about the lower limit of the target range.

Rationale: Although hyperglycemia has been associated with poor outcomes in numerous studies of critically ill children and adults, three prospective multicenter RCTs of glucose control to a low target range (including 50–80, 70–100, 72–126, 80–110 mg/dL or 2.8–4.4, 3.9–5.6, 4.0–7.0, 4.4–6.1 mmol/L) have not demonstrated clinical benefit in children (339–341) (**Supplemental Table 20**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). One single-center RCT did show substantial mortality benefit, but there was a high rate of severe hypoglycemia and the higher target range cohort had substantially higher blood glucose levels than those used in the other multicenter RCTs (342). A trial involving children with burn injuries, a unique PICU population, demonstrated no mortality benefit but did find a significant reduction in morbidity (343). Notably, all trials included sepsis patients but none targeted them exclusively. Meta-analyses of all published prospective trials in children have shown no clinical benefits overall, but showed a substantially higher risk of hypoglycemia when using insulin therapy to maintain a glucose target below 140 mg/dL (7.8 mmol/L) (344, 345). Even brief episodes of severe hypoglycemia during septic shock in children may be a risk factor for poor long-term developmental outcomes (346–349).

Treating hyperglycemia greater than or equal to 180 mg/dL (≥ 10 mmol/L) may be desirable as incidence of insulin-induced hypoglycemia in the studied pediatric cohorts with targets of 140–180 mg/dL (7.8–10.0 mmol/L) is extremely low. There are, however, no direct comparisons between treatment to less than 180 mg/dL (10.0 mmol/L) and no treatment. Therefore, evidence cannot definitively guide this therapeutic target.

However, given that the guidelines for adults recommend an upper limit of 180 mg/dL (10 mmol/L) and given the lack of harm demonstrated in the pediatric trials with those targets, treating children with septic shock or other sepsis-associated organ dysfunction with IV insulin with a goal upper blood glucose target of 180 mg/dL (10 mmol/L) is reasonable. The lower target, that is, the glucose concentration below which insulin infusion should be discontinued, has also not been specifically studied, but is reasonable to set at 140–150 mg/dL (7.8–8.3 mmol/L), based on similar principles. In a survey of our panel members, 32.5% always or often and 17.5% sometimes target glucose levels between 140 and 180 mg/dL. Regardless of the glucose target, the overriding goal during insulin therapy should be avoidance of hypoglycemia.

- 48) We were unable to issue a recommendation as to whether to target normal blood calcium levels in children with septic shock or sepsis-associated organ dysfunction. However, in our practice, we often target normal calcium levels for children with septic shock requiring vasoactive infusion support.

Rationale: Calcium has an essential role in nearly all cellular processes, including myocardial contractility and vasomotor tone. As such, intracellular and circulating levels of calcium are tightly regulated. During septic shock, derangements in calcium regulation frequently occur in critically ill adults and children. However, a systematic review of adult literature found no evidence to support treating hypocalcemia of critical illness (350). Calcium supplementation may actually worsen organ dysfunction and is correlated with adverse outcomes in critically ill adult patients receiving PN (351). Although the prevalence of hypocalcemia in critically ill children has been reported to be up to 75% and is associated with organ dysfunction (352), no studies in children with septic shock have investigated the effect of calcium supplementation to treat hypocalcemia. However, in our practice, 65% of panel members always or often and 20% sometimes target normal calcium levels with parenteral calcium administration in children with septic shock requiring vasoactive infusion support. Only 15% of panel members rarely or never target normal calcium levels.

- 49) We suggest against the routine use of levothyroxine in children with septic shock and other sepsis-associated organ dysfunction in a sick euthyroid state (weak recommendation, low quality of evidence).

Rationale: Critically ill children, similar to adults, develop low tri-iodothyronine (T3) and low normal thyroxine (T4) concentrations without the compensatory rise in thyroid-stimulating hormone that is typical of the “sick euthyroid” state or hypothyroxinemia of nonthyroidal illness (353). The decrease in T3 is due both to increased thyroid hormone turnover and to decreased de-iodination of T4 to T3, with redirection of T4 metabolism toward higher levels of biologically inactive reverse T3. The magnitude of the drop in T3 within the first 24 hours of illness reflects the severity of illness (354). Although of theoretical benefit, few trials of thyroid hormone replacement have been conducted in critically ill children and none in

children with sepsis. Two prospective RCTs in children undergoing cardiac surgery (without sepsis) showed no difference in mortality, vasoactive days, or PICU LOS (355, 356). One open-label study in premature neonates also showed no difference in clinical outcomes (357). Taken together, there are no direct data to inform a recommendation for children with sepsis, and no indirect data from other critically ill children to support a recommendation for the routine use of levothyroxine in children with septic shock and other sepsis-associated organ dysfunction in a sick euthyroid state.

50) We suggest either antipyretic therapy or a permissive approach to fever in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, moderate quality of evidence).

Rationale: Fever is a complex physiologic response associated with sepsis, and it remains unclear whether fever is a beneficial (358) or a harmful (359) response to infection. Potential benefits include inhibiting the growth of some pathogens and increased neutrophil production and lymphocyte proliferation. Conversely, fever is associated with an increased metabolic rate (which may or may not have detrimental effects in patients with sepsis) and may impair some components of immune function. Fever can also make patients uncomfortable (360). Thus, the putative benefits of maintaining normothermia by treating fever are unclear.

No direct evidence for or against the use of antipyretics in febrile children with sepsis-associated organ dysfunction exists. Rather, the panel had to consider indirect data extrapolated from studies in adults. One systematic review of adult patients studied the use of antipyretics and physical cooling methods included eight RCTs (1,507 patients) and eight observational studies (17,432 patients) (361). This study had 28-day mortality as the primary outcome, with additional outcomes of early mortality (i.e., death on or prior to day 14), frequency of acquisition of hospital-acquired infection, frequency of shock reversal, and mean changes in body temperature, heart rate, and minute ventilation. No difference was noted in 28-day mortality. Effects on early mortality differed between the randomized (favored reduced mortality with antipyretic therapy) and observational (favored increased mortality with antipyretic therapy) studies. Although antipyretic therapy successfully decreased body temperature, there was no effect on heart rate, minute ventilation, shock reversal, or acquisition of nosocomial infections. This study did not assess outcome measures of patient comfort. Based on available data, we are not able to recommend the optimal approach to fever in children with sepsis. However, it is reasonable to provide antipyretic therapy to optimize patient comfort, to reduce metabolic demand under certain clinical scenarios (e.g., refractory shock, pulmonary hypertension), and to reduce extreme body temperatures.

NUTRITION

51) We were unable to issue a recommendation regarding early hypocaloric/trophic enteral feeding followed by slow

increase to full enteral feeding versus early full enteral feeding in children with septic shock or sepsis-associated organ dysfunction without contraindications to enteral feeding. However, in our practice, there is a preference to commence early enteral nutrition within 48 hours of admission in children with septic shock or sepsis-associated organ dysfunction who have no contraindications to enteral nutrition and to increase enteral nutrition in a step-wise fashion until nutritional goals are met.

Rationale: No studies examine the enteral nutrition advancement strategy in children with septic shock or other sepsis-associated organ dysfunction. Indirect evidence from a small RCT in critically ill children examines early (6–24 hr) versus late enteral nutrition (> 24 hr) in, respectively, 57 and 52 children (362). Early enteral feeding had no effect on duration of PICU stay, but a trend toward lower mortality in the early feeding group (30% in early feeding vs 48% in late feeding; $p = 0.07$) was shown. There is also indirect evidence from the EDEN trial in adults (363) in which 200 patients were randomized to receive either trophic or full enteral feeding for the first 6 days. This study demonstrated no difference in number of ventilator-free days, mortality at 60 days, or infectious complications, but trophic enteral feeding was associated with less gastrointestinal intolerance. Because neither of these studies was conclusive nor directly studied children with septic shock or other sepsis-associated organ dysfunction, no evidence-based recommendation could be made by the panel. However, in critically ill children, a step-wise approach to increasing enteral feeds has been shown to reduce time needed to reach nutritional goals (364–367). In our practice, 60% of panel members always or often and 20% sometimes commence early enteral feeding within 48 hours of admission in children with septic shock or sepsis-associated organ dysfunction who have no contraindications to enteral nutrition, while 20% of panel members rarely or never pursue this practice.

52) We suggest not withholding enteral feeding solely on the basis of vasoactive-inotropic medication administration (weak recommendation, low quality of evidence).

Remarks: Enteral feeding is not contraindicated in children with septic shock after adequate hemodynamic resuscitation who no longer require escalating doses of vasoactive agents or in whom weaning of vasoactive agents has started.

Rationale: We reviewed indirect evidence from three observational studies (two retrospective and one prospective) in postoperative/cardiac pediatric populations. These studies reported that enteral feeding was tolerated in patients on nonescalating/weaning doses of vasoactive agents without increased adverse effects or gastrointestinal complications (368–370). In another study of 339 critically ill children, there was no association between enteral feeding and the development of severe gastrointestinal outcomes such as vomiting, diarrhea, abdominal distension, bleeding, necrotizing enterocolitis, or perforation (368). However, in the report, the decision to start enteral nutrition may have been biased by the clinical condition of

the patient. In a retrospective study of 52 critically ill children, the use of vasoactive medications was not associated with an increase in feeding intolerance or gastrointestinal complications (369). In a prospective observational study of critically ill children who received postpyloric feeding, 44 of 65 patients (67.7%) with shock and 284 of 461 patients (61.6%) without shock received enteral nutrition within 48 hours. Although gastrointestinal complications were more common in children admitted with shock, no association between the incidence of digestive tract complications and early (first 48 hr) or late administration of postpyloric enteral nutrition was reported (370). Based on these studies which, while providing indirect evidence, all consistently found that enteral feeding was not associated with harm, we recommend not to withhold enteral nutrition solely because vasoactive-inotropic medications are being used. Current evidence supports starting enteral nutrition in hemodynamically stable patients who are no longer requiring fluid resuscitation or escalating doses of vasoactive agents.

53) We suggest enteral nutrition as the preferred method of feeding and that parenteral nutrition may be withheld in the first 7 days of PICU admission in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, moderate quality of evidence).

Rationale: No studies have been published on this specific issue of nutrition in children with septic shock or other sepsis-associated organ dysfunction. However, in a general cohort of 1,440 critically ill children enrolled in the international multicenter RCT of pediatric early versus late PN in critical illness (371), withholding parenteral nutrition during the first week in PICU when enteral nutrition was less than 80% of prescribed goal was clinically superior to providing supplemental parental nutrition within 24 hours of admission (372). Secondary analyses of the PEPaNIC trial showed that withholding PN was also beneficial in term neonates and children who were undernourished at admission (373, 374), although withholding parenteral nutrition in term neonates was also associated with increased risk of severe hypoglycemia (373). A long-term follow-up 2 years after PICU admission showed that withholding parenteral nutrition for 1 week did not affect survival, anthropometrics, or health status, but did improve certain domains of neurocognitive development (375). Although the results of the PEPaNIC trial corroborated the findings from adult RCTs, the optimal timing of parenteral nutrition in the critically ill child with sepsis is still not clear (371, 376–378). Our recommendation is based on one trial, and therefore, the evidence to withhold PN in the first 7 days of PICU admission is of moderate certainty and must be explored further using pragmatic timing for PN in the first week, particularly in severely malnourished patients and neonates.

54) We suggest against supplementation with specialized lipid emulsions in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence).

Rationale: In two RCTs evaluating immunomodulatory formulas, including lipid emulsions, in critically ill children, outcomes were not significantly different (379, 380). One RCT was terminated during interim analysis because of unlikely benefit in the intervention arm (380). In another small RCT, use of enteral feeding supplemented with or without omega-3 fatty acids in 120 critically ill children with sepsis was investigated (381). Univariate analyses showed a significant difference in inflammatory mediators and reduction in PICU LOS, but these outcome benefits were not evident in the multivariable analyses. Taken together, although promising, insufficient evidence is available to support routine supplementation in pediatric sepsis with specialized lipid emulsions.

55) We suggest against the routine measurements of gastric residual volumes (GRVs) in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Rationale: Although routine measurement of GRV is a relatively common practice in PICUs, there is no direct evidence in pediatric sepsis. In a two-center observational cohort study of critically ill children admitted with a variety of diagnoses, one center reported routine use of GRV monitoring while the other center did not practice GRV measurements (382). The center that advanced enteral nutrition without routine measurements of GRV did not have an increase in the incidence of vomiting, ventilator acquired pneumonia, or necrotizing enterocolitis in comparison with the other PICU (**Supplemental Table 21**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Although there are likely some children for whom measuring GRV would likely be useful (e.g., gastroparesis, omphalocele, gastroschisis), no evidence supports routine measurements in all patients at this time and, if measured, GRV is not sufficient to diagnose EN intolerance.

56) We suggest administering enteral feeds through a gastric tube, rather than a postpyloric feeding tube, to children with septic shock or other sepsis-associated organ dysfunction who have no contraindications to enteral feeding (weak recommendation, low quality of evidence).

Rationale: In three small RCTs, gastric versus postpyloric enteral feeding were compared in mechanically-ventilated children with a variety of diagnoses (383–385). The outcomes reported included lower caloric achievement with gastric feeding and delayed start of enteral feeding with postpyloric feeding (383, 384). No significant difference was found in the incidence of ventilator-associated pneumonia between gastric and postpyloric feeding (385). On the basis of these studies, there is no clear evidence that postpyloric feeding is beneficial and there is concern for potential harm through delayed optimization of enteral nutrition. Therefore, we suggest that feeding with a gastric tube is physiologic and, based on current evidence, the preferred method for enteral nutrition. Postpyloric feeding may be considered in patients in whom gastric feeding is either contraindicated (e.g., high-risk for aspiration)

or was not tolerated/advanced, and as a result, nutritional goals were unable to be met.

57) We suggest against the routine use of prokinetic agents for the treatment of feeding intolerance in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Rationale: Prokinetic agents, such as metoclopramide and erythromycin, are often used in the PICU in an effort to reduce feeding intolerance (386). Indirect evidence for this question was provided from the only pediatric randomized control trial, which was a combined intervention of enteral zinc, selenium, glutamine, and IV metoclopramide. In critically ill children, this combined intervention failed to reduce the development of sepsis or incidence of hospital-acquired infection in immunocompetent children, although the intervention including metoclopramide did reduce the rate of hospital-acquired infection and sepsis in immunocompromised children. However, the application of this study to children who already have sepsis is not clear. Prokinetic agents are also not without risk as they have been associated with prolongation of the QT interval and ventricular arrhythmias (387–389). Further investigation is needed to determine if prokinetic agents are beneficial in patients with sepsis, particularly in immunocompromised children.

58) We suggest against the use of selenium in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Rationale: Although clinical research examining the use of selenium among critically ill neonates and adults has been done (Supplemental Table 22, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>), there no data regarding selenium supplementation as potential adjunctive therapy for pediatric sepsis. Selenium plays a key role as a cofactor for glutathione peroxidase, iodothyronine deiodinase, and thioredoxin (390); accordingly, selenium deficiency could affect thyroid metabolism and the response to oxidative stress during critical illness. Furthermore, low serum selenium concentrations are common in critical illness (391, 392) and infection (393), and have been associated with measures of oxidative stress in neonates (394) and adults (395).

A systematic review of investigations examining selenium supplementation in preterm neonates reported improved outcomes, including reduction in occurrence of sepsis (396). Similarly, a published systematic review and meta-analysis of the effect of parenteral selenium supplementation in critically ill adult sepsis patients concluded that this intervention reduced risk of mortality (397), but when the meta-analysis was updated to include the results of a more recent RCT, there was no difference in mortality in those treated with or without selenium supplementation (50). In an interventional trial examining the potential benefit of zinc, selenium, glutamine, and metoclopramide administration to critically ill children, there was no reduction in the primary outcome measure, namely, time until the first episode of nosocomial infection/sepsis (380). Based on lack of interventional trials examining

selenium supplementation in the setting of pediatric sepsis and sepsis-associated organ dysfunction, we suggest against its use as a weak recommendation.

59) We suggest against the use of glutamine supplementation in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Rationale: During catabolic stress, the human body is unable to produce adequate quantities of glutamine and, therefore, its essential role as a fuel source for enterocytes and immune cells is diminished. Over the past 2 decades, several investigations of glutamine administration alone and in various combinations with other nutritional supplements have been conducted in critically ill populations (380, 398–404), including those with sepsis (399, 405–407). Contemporary studies have not found glutamine in any form (enteral or parenteral) and/or in combination with other nutritional elements to significantly improve morbidity or mortality in critically ill infants, children, and adults, including those with sepsis (408–410) (Supplemental Table 23, Supplemental Digital Content 1, <http://links.lww.com/PCC33/B138>). However, single-element studies administering only glutamine to children with sepsis and septic shock are scarce. An RCT by Jordan et al (401) randomized children (49 control; 49 interventional) with sepsis and septic shock requiring PN to either standard PN or PN with glutamine supplementation for the purpose of examining oxidative stress and inflammatory response. This investigation supports earlier studies in broader populations finding no differences in PICU ($p = 0.062$) or hospital LOS ($p = 0.09$) or hospital mortality ($p = 0.31$). Two other studies of glutamine administration in combination with other elements to children with septic shock and critical illness are available (380, 399). The RCT by Briassoulis et al (399) examined children with septic shock receiving glutamine in combination with arginine, antioxidants, and omega-3 fatty acids. Although the main outcome of change in cytokines showed some promise, no difference was noted between groups for hospital survival (80% vs 87%) or LOS (10.4 ± 2.2 vs 11.4 ± 2.5 d) (15). Carcillo et al (380) randomized 283 subjects from eight PICUs to a control group receiving whey protein formula or an intervention group receiving formula with zinc, selenium, glutamine, and IV metoclopramide supplementation. There was no difference between hospital-acquired infections and clinical sepsis per 100 days ($p = 0.81$), PICU LOS ($p = 0.16$), or 28-day mortality (8/139 [5.8%] vs 15/145 [10.3%]). Subjects from this trial were also categorized by immune status with the suggestion that immune status may play a role in the effectiveness of nutritional supplemental, including glutamine (411). However, no direct evidence regarding glutamine supplementation in children with sepsis exists; hence, we suggest against the use of glutamine therapy in children with septic shock or other sepsis-associated organ dysfunction until further data become available.

60) We suggest against the use of arginine in the treatment of children with septic shock or other sepsis-associated organ

dysfunction (weak recommendation, very low quality of evidence).

Rationale: Reduced availability of arginine in sepsis may lead to decreased endogenous nitric oxide synthesis, loss of microcirculatory regulation, and altered immune response (412–414). In the only pediatric RCT of arginine supplementation in children with sepsis (415), 10 children received infusions of arginine and had enhanced arginine oxidation and increased nitric oxide levels, but no clinical outcomes were reported. In indirect data from adult studies, RCTs of L-arginine supplementation have been small and have reported both positive and negative effects on mortality (416–420). One trial in septic adults found decreased mortality (418), but other studies found no benefit or increased mortality in adults with sepsis (416, 419, 420). Some authors found improvement in secondary outcomes in patients with sepsis, such as reduced infectious complications and shorter LOS, but the relevance of these findings and their applicability to children with sepsis in the face of potential harm is unclear. Hence, in the absence of evidence of demonstrated benefit, we suggest against the use of arginine therapy in children with sepsis-associated organ dysfunction until further data become available.

61) We suggest against using zinc supplementation in children with septic shock and other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence).

Rationale: Alterations in zinc homeostasis and associations between zinc levels and outcomes have been reported in the critically ill. Benefits of zinc supplementation have been shown in some forms of infectious illnesses. However, no trials of zinc supplementation in children with sepsis have been conducted. One RCT in critically ill children comparing daily supplementation with zinc, selenium, glutamine, and metoclopramide versus whey protein was stopped during interim analysis due to futility (380). Based on conflicting studies in the adult literature, routine supplementation of zinc is not recommended in nutritional guidelines for critically ill adults (421). Future RCTs examining the optimal timing and dose of zinc in children with sepsis and septic shock and its impact on immune response and clinical outcomes might help answer this question.

62) We suggest against the use of ascorbic acid (vitamin C) in the treatment of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence).

Rationale: Ascorbic acid (vitamin C) has multiple physiologic functions. Most importantly in the setting of sepsis, vitamin C is an antioxidant and neutralizes reactive oxygen and nitrogen radicals, inhibits activation of pro-inflammatory cytokines, increases endogenous vasopressor synthesis, and inhibits bacterial replication (422–424). Adults with sepsis frequently have very low levels of vitamin C. In one study, 88% of adults with septic shock had hypovitaminosis C (425). Small studies in adults suggest that treatment of septic patients with vitamin C may improve organ dysfunction (426) and reduce mortality (427). Vitamin C has also been used as a component of combination therapy, typically

with thiamine and corticosteroids, in adults with sepsis (428). One study compared such treatment in 47 adult patients with sepsis to historical control patients (429). Treatment was associated with decreased hospital mortality (OR, 0.13; 95% CI, 0.04–0.48), shorter duration of vasopressor therapy, and improved organ dysfunction scores (**Supplemental Table 24**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

Currently, there are no data on the use of vitamin C in critically ill children or in pediatric sepsis. The prevalence of low vitamin C levels in septic children is unknown, and no studies have investigated the effect of vitamin C supplementation, either alone or in combination with other agents, in the treatment of pediatric sepsis.

63) We suggest against the use of thiamine to treat children with sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Rationale: Thiamine is a crucial factor in cellular metabolism. In its active form, thiamine pyrophosphate is an essential coenzyme used to generate energy (adenosine triphosphate) from glucose. The human body does not produce thiamine and, with a short half-life and small body stores, thiamine deficiency can develop within days of critical illness and inadequate nutrition, resulting in impaired oxidative and carbohydrate metabolism. Low blood concentrations of thiamine have been reported at admission of critically ill children and adults with sepsis and septic shock (430–432). A study examining thiamine deficiency in children admitted to the PICU showed that low blood thiamine concentration in those with severe sepsis or septic shock was associated with mortality (OR, 8.40; 95% CI, 1.38–51.0) (431). In an RCT of 88 adults with septic shock (**Supplemental Table 25**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>), there were no differences between treatment with thiamine versus placebo for the primary outcome of change in lactate levels or the secondary outcomes of mortality, shock reversal, and LOS (430). However, on post hoc analysis, thiamine treatment in the subgroup with thiamine deficiency at admission was associated with lower lactate level within 24 hours and lower mortality ($p = 0.047$). However, more evidence is needed to recommend whether thiamine supplementation should be used to treat children with septic shock or other sepsis-associated organ dysfunction. Also, it may be important for this evidence to be considered in the context of thiamine status at PICU admission.

64) We suggest against the acute repletion of vitamin D deficiency (VDD) for treatment of septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence).

Rationale: A systematic review and meta-analysis of 17 studies including 2,783 patients showed that approximately half of critically ill children have VDD (25-hydroxy vitamin D level < 50 nmol/L or < 20 ng/mL) at PICU admission (189). Further, VDD was associated with higher illness severity, multiple organ dysfunction, and mortality across these studies. Six of these studies focused on or separately analyzed children

with sepsis (433–437). Three studies reported a greater need for vasoactive agents in VDD children (433–435), although mortality across these six studies was not associated with VDD (433–437) (**Supplemental Table 26**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

Vitamin D levels are lowered by fluid resuscitation, which can confound the association with illness severity and disease complications (434). In addition, free or bioavailable $1,25(\text{OH})_2\text{D}$ is the active form which is influenced by the level of vitamin D binding protein (VDBP) and a patient's VDBP genotype, which was not estimated or measured in prior studies (438). Although vitamin D levels are a potentially modifiable risk factor via supplementation, a meta-analysis of rapid normalization of vitamin D levels concluded that it is best achieved using loading therapy that takes into account disease status, determines baseline vitamin D level, and considers patient weight (439–441). A loading dose greater than 300,000 international units should be avoided outside of RCTs evaluating risk and benefit.

Hypervitaminosis D is associated with hypercalcemia and other severe complications (442) and vitamin D overdoses can be fatal (443). No current data support that rapid acute correction of VDD is an effective treatment in septic shock or improves outcomes of septic children. Further, measurement of $25(\text{OH})_2\text{D}$ levels is not currently a standard component of sepsis care and methods of accurately measuring bioavailable vitamin D are not yet widely validated. However, if VDD is diagnosed, repletion should occur as a usual part of general holistic pediatric care according to recommended guidelines independently of the presence of sepsis (444).

BLOOD PRODUCTS

65) We suggest against transfusion of RBCs if the blood hemoglobin concentration is greater than or equal to 7 g/dL in hemodynamically stabilized children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Remarks: According to the 2018 Transfusion and Anemia Expertise Initiative (TAXI) guidelines, for the purposes of RBC transfusion, “hemodynamically stabilized” is defined as a MAP higher than 2 SDs below normal for age and no increase in vasoactive medications for at least 2 hours.

66) We cannot make a recommendation regarding hemoglobin transfusion thresholds for critically ill children with unstable septic shock.

Rationale: The only study evaluating specific RBC transfusion thresholds in children with sepsis is a post hoc subgroup analysis of the Transfusion Requirements in the PICU (TRIPICU) study (445) (**Supplemental Table 27**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). This study included 137 stabilized critically ill children (MAP > 2 SDs below normal for age and cardiovascular support not increased for at least 2 hr before enrollment) with sepsis, with a hemoglobin less than or equal to 9.5 g/dL within 7 days after PICU admission. Patients were randomized to receive RBCs if hemoglobin

decreased to either less than 7.0 g/dL (restrictive group) or 9.5 g/dL (liberal group). No differences were found between the restrictive versus liberal group in the primary endpoint of new or progressive multiple organ dysfunction syndrome (18.8% vs 19.1%) or mortality ($p = 0.44$). These results are similar to those from primary analysis of the TRIPICU study (446), as well as in adults (447). Our suggestion against transfusion if hemoglobin is greater than 7 g/dL in hemodynamically stable children with sepsis parallels the TAXI recommendations (448).

Insufficient data are available to guide RBC transfusion therapy in children with unstable septic shock. Two pediatric RCTs did demonstrate decreased mortality when red blood transfusion to goal hemoglobin greater than or equal to 10 (hematocrit > 30%) was included as part of an EGDT algorithm targeting Scvo_2 , but the impact of each individual component, including red blood transfusion, is unclear (190, 449). In critically ill adults, the Transfusion Requirements in Septic Shock trial randomized 998 subjects with septic shock to either a transfusion threshold hemoglobin of 7 g/dL or 9 g/dL (450). At randomization, all patients had hypotension (mean arterial pressure < 70 mm Hg) and/or were being treated with vasopressors. Ninety-day mortality showed no differences (RR, 0.94; 95% CI, 0.78–1.09), suggesting that a restrictive transfusion strategy in hemodynamically unstable septic adults was safe (**Supplemental Table 27**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). The SSC recommends that RBC transfusion in adults occur only when hemoglobin concentration decreases to less than 7.0 g/dL in the absence of extenuating circumstances, such as myocardial ischemia, severe hypoxemia, or acute hemorrhage (strong recommendation, high quality of evidence) (50). This adult recommendation is also valid for hemodynamically unstable patients.

However, in the absence of pediatric data, we are not able to provide a recommendation for critically ill children with unstable septic shock.

67) We suggest against prophylactic platelet transfusion based solely on platelet levels in nonbleeding children with septic shock or other sepsis-associated organ dysfunction and thrombocytopenia (weak recommendation, very low quality of evidence).

Rationale: One observational study demonstrated an association between the administration of platelet transfusions to critically ill children and worse clinical outcomes (**Supplemental Table 28**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>), including longer ICU LOS, progressive organ dysfunction, and increased mortality (451). Indirect evidence can be found in an RCT of 660 infants born at less than 34 weeks gestational age, the majority of whom were treated for sepsis, that compared a platelet transfusion threshold of $50,000/\text{mm}^3$ (high threshold) with $25,000/\text{mm}^3$ (low threshold) (452). More infants in the high- versus low-threshold group received at least one platelet transfusion (90% vs 53%). More adverse events, including new major bleeding or death, were also seen in the high threshold group (OR, 1.57; 95% CI, 1.06–2.32).

Although existing evidence does not support a platelet threshold at which transfusion is absolutely indicated, the risk of spontaneous bleeding may be greater at lower platelet counts, for example, less than 10–20,000/mm³. In addition, some populations of thrombocytopenic critically ill children may have a relatively high risk of bleeding, such as those with oncological diagnoses or those receiving ECMO. Because the threshold at which the benefits of platelet transfusion outweigh the risks is unknown, clinical judgment based on patient risk factors for bleeding in addition to the measured platelet level must be exercised carefully.

68) We suggest against prophylactic plasma transfusion in nonbleeding children with septic shock or other sepsis-associated organ dysfunction and coagulation abnormalities (weak recommendation, very low quality of evidence).

Remarks: Prophylactic plasma transfusion refers to situations in which there is an abnormality in laboratory coagulation testing but no active bleeding.

Rationale: No direct data exist to inform a recommendation about plasma transfusion in pediatric sepsis. One RCT evaluates prophylactic plasma transfusion in critically ill children without sepsis. Pieters et al (453) randomized 81 children less than 2 years old requiring primary repair of craniosynostosis to receive plasma using either a prophylactic (in absence of bleeding) or reactive (when the patient was bleeding) strategy. The prophylactic plasma transfusion group received a significantly higher volume of plasma compared with the reactive group (29.7 vs 16.1 mL/kg; $p < 0.001$). Despite an improvement in coagulation values in the prophylactic group, there was no difference in packed RBC transfusion requirements or blood loss between the two groups (**Supplemental Table 29**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Additionally, a meta-analysis published in 2012 that included 80 RCTs (mostly in adults) concluded that there was no consistent evidence for benefit of prophylactic plasma transfusion across a range of indications that were evaluated (454). Observational studies in critically ill children have shown that plasma transfusions are associated with worse clinical outcomes (455, 456). Furthermore, plasma transfusion frequently fails to correct abnormal coagulation tests in critically ill adults and children (456, 457). We therefore suggest against prophylactic plasma transfusions for children with septic shock and other sepsis-associated organ dysfunction who are not bleeding.

However, some specific patient populations might benefit from prophylactic plasma transfusions, such as patients with worsening coagulation tests at high risk for disseminated intravascular coagulopathy, children with comorbid cancer, or children with sepsis on extracorporeal life support.

PLASMA EXCHANGE, RENAL REPLACEMENT, AND EXTRACORPOREAL SUPPORT

69) We suggest against using plasma exchange (PLEX) in children with septic shock or other sepsis-associated organ dysfunction without thrombocytopenia-associated multiple

organ failure (TAMOF) (weak recommendation, very low quality of evidence).

70) We cannot suggest for or against the use of PLEX in children with septic shock or other sepsis-associated organ dysfunction with TAMOF.

Rationale: Therapeutic PLEX for septic shock or sepsis-associated organ dysfunction aims to normalize the plasma milieu of a systemically inflamed septic patient. Currently, no large RCTs have evaluated PLEX in pediatric septic shock or sepsis-associated organ dysfunction. Rimmer et al (458) performed a meta-analysis that included four small RCTs evaluating PLEX in adults ($n = 128$) and pediatric ($n = 66$) patients with sepsis and septic shock. PLEX was associated with reduced mortality in adults (RR, 0.63; 95% CI, 0.42–0.96), but not in children (RR, 0.96; 95% CI, 0.28–3.38). However, because of the heterogeneity of the patient population, inclusion criteria, technical modalities of PLEX (filtration vs centrifugation), and types of replacement fluid (plasma vs albumin) in these four studies as well as the costs and potential risks, PLEX cannot be routinely recommended as this time (**Supplemental Table 30**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Similarly, the American Society for Apheresis recommended that the “optimum role of apheresis therapy is not established” in sepsis with multiple organ failure (459).

TAMOF is an inflammatory phenotype of sepsis-induced multiple organ dysfunction in children that can be identified clinically by new-onset thrombocytopenia and evolving multiple organ dysfunction (460, 461). Autopsies performed on patients who died with TAMOF revealed disseminated microvascular thromboses in various organs (460). These patients had deficient activity of a disintegrin and metalloproteinase with thrombospondin type 1 motif (ADAMTS-13), elevated von Willebrand factor (VWF) activity, and the presence of ultra-large plasma VWF (460, 462). Decreased activity of ADAMTS-13 leads to high circulating levels of ultra-large VWF that induce widespread platelet activation and thrombotic microangiopathy. A number of inflammatory mediators are elevated in sepsis that can inhibit or inactivate ADAMTS-13 including interleukin-6, granulocyte elastase, plasmin, thrombin, cell-free hemoglobin, Shiga toxins, and immunoglobulin G auto-antibody (463–468).

Three studies have examined the utility of PLEX in children with sepsis and TAMOF (460, 469, 470). In the most recent and largest study ($n = 81$), Fortenberry et al (469) reported that PLEX was associated with lower 28-day mortality by multivariate analysis (adjusted RR, 0.45; 95% CI, 0.23–0.90) and by propensity score weighting (adjusted RR, 0.46; 95% CI, 0.22–0.97). In a retrospective cohort study from the Turkish TAMOF Network ($n = 42$), PLEX was associated with lower 28-day mortality compared with the no PLEX group (27% vs 70%; $p = 0.004$) [470]). In the third study, Nguyen et al (460) randomized 10 children to either PLEX or standard therapy. The 5 patients who received PLEX had restoration of ADAMTS-13 activity and greater survival (5/5) compared with standard therapy (1/5; $p < 0.05$). Taken together, these data support a biologic rationale for the use of PLEX in

TAMOF, that is, the removal of pathologic ultra-large VWF and ADAMTS-13 inhibitors and restoration of ADAMTS-13 activity. This approach of using PLEX is similar to the rationale for using PLEX in thrombotic thrombocytopenic purpura (471). Although the panel acknowledges a potential benefit for PLEX and encourages an RCT to better define the utility of PLEX in children with sepsis and TAMOF, a recommendation could not be made based on existing data.

71) We suggest using renal replacement therapy to prevent or treat fluid overload in children with septic shock or other sepsis-associated organ dysfunction who are unresponsive to fluid restriction and diuretic therapy (weak recommendation, very low quality of evidence).

Rationale: Renal replacement therapy is increasingly being used in PICUs for renal and nonrenal conditions. The rationale for renal replacement therapy in septic shock includes impending or established fluid overload following initial resuscitation or for cytokine removal, reversal of coagulopathy, to buffer lactic acidosis, to address AKI, or a combination of these factors. CRRT may be useful for treating established fluid overload or to prevent further fluid overload while allowing liberal volume administration for nutrition, antimicrobials, and other medications, sedation, and transfusions. In addition, certain techniques of continuous blood purification may help to regulate systemic inflammation and promote kidney recovery (472). Fluid overload has been shown to cause increased morbidity and mortality in various intensive care settings, and there is documented favorable association of CRRT in fluid overload (473).

However, no high-quality studies in critically ill children with sepsis exist to directly determine whether RRT is definitively beneficial compared with diuretics and/or fluid restriction. Most of the data come from adult studies where outcomes have varied from mortality to ICU LOS and ventilator- and vasoactive-free days. One study addressed the timing of CRRT initiation in 27 children with sepsis and multiple organ dysfunction, demonstrating that CRRT was associated with survival when started within 48 hours of admission compared with those started on CRRT after 48 hours of admission (61% vs 33%; $p < 0.001$). However, timing of CRRT initiation was at the discretion of the treating team, raising concern for confounding between groups, and all patients in both groups experienced normalization of kidney function (474) (**Supplemental Table 31**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

The possible benefits of CRRT must also be weighed against potential risks, including the need for an invasive catheter, costs, limited availability in some centers, the need for clinician and nursing-specialist expertise, and the challenge of optimal timing (e.g., following resuscitation for fluid removal or earlier for acute cytokine clearance). Therefore, as the initial treatment strategy, we judge that fluid restriction and use of diuretics are reasonable in the presence of impending or established fluid overload with CRRT reserved as a second-line option to prevent or treat fluid overload in children with septic shock or

other sepsis-associated organ dysfunction who are unresponsive to fluid restriction and diuretic therapy.

72) We suggest against high-volume hemofiltration (HVHF) over standard hemofiltration in children with septic shock or other sepsis-associated organ dysfunction who are treated with renal replacement therapy (weak recommendation, low quality of evidence).

Rationale: HVHF for critically ill patients with septic shock and AKI is an appealing strategy for maintaining acid-base and fluid homeostasis, or for having a potential immunomodulatory effect in sepsis by removal of toxins and other inflammatory mediators, especially cytokines that contribute to organ injury and dysfunction.

In adults, use of higher CRRT flux rates (> 35 mL/kg/hr filtration-dialysis), while initially encouraging, has not shown overall mortality benefit in subsequent RCTs and meta-analysis. A 2017 Cochrane review found no significant benefit in mortality, severity of organ dysfunction, LOS, or adverse effects with HVHF versus standard hemofiltration rates in critically ill adults (475). Notably, the results of this meta-analysis show that very few studies have been conducted to investigate the use of HVHF in critically ill patients with septic shock (four studies totaling 201 participants).

In a study involving 155 pediatric patients with severe sepsis, HVHF treatment did not significantly reduce 28-day mortality compared with standard volume CRRT. Furthermore, there were no significant reductions in plasma levels of inflammatory mediators or in improving hemodynamic variables for HVHF. However, the incidence of hyperglycemia was significantly higher in HVHF group than in CVVH group (476) (**Supplemental Table 32**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

73) We suggest using venovenous ECMO in children with sepsis-induced PARDS and refractory hypoxia (weak recommendation, very low quality of evidence).

Rationale: ECMO was introduced more than 40 years ago to support patients with reversible but severe cardiovascular and/or respiratory failure refractory to conventional medical therapy. As such, children with life-threatening sepsis-induced ARDS are often considered as candidates for ECMO rescue (477), and PALICC endorsed ECMO for the treatment of refractory hypoxia (24). The use of ECMO in pediatric sepsis has increased over the past decade (478, 479); whether this has improved survival remains to be determined (480). To date, no RCT examining the effect of ECMO on outcome in pediatric sepsis has been published. In the absence of such data, using propensity score matching, Barbaro et al (481) reported that children with severe PARDS enrolled in the RESTORE trial had similar mortality rates when supported with ECMO (15/61, 25%) as compared with those who were not (18/61, 30%) (482) (**Supplemental Table 33**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). Research is underway to determine optimal pre-ECMO candidacy (483) as measures of renal, hepatic, neurologic, and hematologic

dysfunction, and particularly the presence of bloodstream infections, seem to discriminate mortality risk better than traditional pediatric severity of illness scores such as PRISM, Pediatric Index of Mortality, and Pediatric Logistic Organ Dysfunction. Clearly, ECMO is not available worldwide, and transfer of highly unstable patients to higher levels of care that offer the therapy can carry substantial risk. However, adult and pediatric data suggest a potential association with improved mortality, particularly if transfer is to high volume ECMO centers (484, 485).

74) We suggest using venoarterial ECMO as a rescue therapy in children with septic shock only if refractory to all other treatments (weak recommendation, very low quality of evidence).

Rationale: Several anecdotal reports of use of venoarterial ECMO in the management of RSS in children exist. More recent reports suggest that venoarterial ECMO may be associated with better survival than conventional therapy, and strategies to maximize flow rates to reverse shock and multiple organ dysfunction may play an important role (486, 487). However, considerable concern surrounds the risks of this highly invasive therapy, such as hemorrhage and thromboembolic events.

The most recent and largest report of venoarterial ECMO in 44 pediatric patients with RSS secondary to bacterial, viral, or fungal infection admitted to seven tertiary PICUs across five different countries compared their outcome to 120 children with RSS managed by conventional therapy (488). Inclusion in the study required children to meet three of four criteria for severe septic shock in the first 24 hours of their ICU stay: arterial pH less than or equal to 7.15, arterial lactate greater than or equal to 4.0 mmol/L, base excess less than or equal to -10 mmol/L, and in-hospital cardiac arrest. Patients were excluded if they had cyanotic congenital heart disease, myocarditis, or an out-of-hospital cardiac arrest. The results showed no significant difference in survival to hospital discharge (50% in the venoarterial ECMO cohort vs 40% in the conventional therapy cohort). Survival was significantly higher in patients who received high ECMO flows (> 150 mL/kg/min at 4 hr after institution of ECMO) compared with children who received standard ECMO flows or no ECMO (**Supplemental Table 34**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

The potential use of venoarterial ECMO for RSS suggests that the definition of RSS should be standardized across institutions. As yet, no universal definition of RSS in children exists. One published definition that could be applied is from the European Society of Paediatric and Neonatal Intensive Care (10). The suggested definition for RSS was blood lactate greater than 8 mmol/L or a 1 mmol/L lactate increase after 6 hours of resuscitation and high vasoactive dependency (vasopressor-inotrope score > 200), or myocardial dysfunction defined as the occurrence of a resuscitation-responsive cardiac arrest in PICU or cardiac ultrasound findings with left

ventricle ejection fraction less than 25% or a cardiac index less than 2.2 L/min/m².

IMMUNOGLOBULINS

75) We suggest against the routine use of IV immune globulin (IVIG) in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence).

Remarks: Although routine use of IVIG is not recommended, select patients may benefit from such treatment.

Rationale: The proposed rationale for IVIG in severe infections is to boost passive immunity through neutralization of bacterial toxins, promoting opsonization of bacteria, and inhibition of immune cell proliferation and inflammatory mediators. However, IVIG has considerable batch-to-batch variability and its true biologic activity is not clear. There are no high-quality studies of IVIG in critically ill children with sepsis, and small observational studies have reported conflicting results (489). An RCT of polyclonal IVIG in 100 children with sepsis demonstrated a reduction in mortality (28% vs 44%), LOS (6 vs 9 d), and less progression to complications (8% vs 32%) (490). However, a more recent multicenter trial of polyclonal IVIG in 3,493 neonates with suspected or proven serious infection found no significant differences in mortality or major disability (491). Other studies have been carried out with specific monoclonal antibodies (e.g., monoclonal antibody against endotoxin in children with meningococcal septic shock), but there are no definitive data to support general benefit of polyclonal immunoglobulin in neonates or children with septic shock at this time. Data from adult patients with septic shock also do not support a routine benefit of IVIG (492), although administration of immunoglobulin M- and immunoglobulin A-enriched polyclonal IVIG has shown possible efficacy (493) (**Supplemental Table 35**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

For patients with toxic shock syndrome, especially those with streptococcal etiology, polyclonal IVIG may have clinical utility (494). Other potential pediatric populations that may benefit from IVIG in sepsis are those with necrotizing fasciitis (although evidence in adults does not support use [495, 496]), and those with primary humoral immunodeficiencies or immunocompromised with documented low immunoglobulin levels.

PROPHYLAXIS

76) We suggest against the routine use of stress ulcer prophylaxis in critically ill children with septic shock or other sepsis-associated organ dysfunction, except for high-risk patients (weak recommendation, very low quality of evidence).

Remarks: Although routine stress-ulcer prophylaxis is not recommended, some high-risk patients may benefit from

stress ulcer prophylaxis. Studies have supported benefit of stress-ulcer prophylaxis when baseline rate of clinically important bleeding is approximately 13%.

Rationale: Stress ulcer prophylaxis should not be routinely administered to children with septic shock or other sepsis-associated organ dysfunction, as evidence for benefit is lacking (497) and may increase risk of adverse effects, such as pneumonia or *C. difficile* (formerly *Clostridium*) infection (498). Rather than routine, universal administration of stress-ulcer prophylaxis, individual patients should be assessed for the presence of risk factors of clinically important gastrointestinal bleeding. These include multiple organ dysfunction (499), prolonged mechanical ventilation (> 48 hr), coagulopathy, persistent shock, and treatment with corticosteroids and nonsteroidal anti-inflammatory agents (500).

The risk of GI bleeding is also reduced by mucosal protection introduced by gastric feeding. Early enteral nutrition could therefore be a viable alternative to pharmacological stress-ulcer prophylaxis. A meta-analysis of 1,836 adult patients reported that, in the presence of enteral nutrition, pharmacological stress ulcer prophylaxis did not significantly change the risk of GI bleeding. Notably, in those patients who received enteral nutrition and were treated with stress ulcer prophylaxis, the risk of pneumonia was increased compared with patients not treated with stress ulcer prophylaxis (OR, 2.81; 95% CI, 1.2–6.6) (501) (**Supplemental Table 36**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>).

77) We suggest against routine deep vein thrombosis (DVT) prophylaxis (mechanical or pharmacologic) in critically ill children with septic shock or other sepsis-associated organ dysfunction, but potential benefits may outweigh risks and costs in specific populations (weak recommendation, low quality of evidence).

Rationale: An open-label RCT of low molecular weight heparin to prevent CVC-associated thrombosis in the PICU was terminated early because of poor recruitment (502). Eleven of 78 patients (14.1%) randomized to reviparin had DVT proven on venogram versus 10 of 80 controls (12.5%) (OR, 1.15; 95% CI, 0.42–3.23). Three adverse events (major bleed or death) all occurred in the control group and no deaths occurred because of venous thromboembolism (**Supplemental Table 37**, Supplemental Digital Content 1, <http://links.lww.com/PCC/B138>). A subsequent systematic review found the quality of evidence to be low and that the efficacy of low molecular weight heparin in preventing CVC-associated thrombosis is unknown (503). It is important to highlight that these studies were specific to children with CVCs who may or may not have had sepsis and that they may not apply to the general thromboembolic risk in children with sepsis.

Although CVCs represent the principal risk factor for DVT in infants (504), older children may have other risk factors. For example, the risk of DVT increases in adolescence, obesity, cancer, and in those with multiple medical

conditions, especially renal and cardiac disease (505, 506). At present, it is unknown whether certain high-risk populations of children with sepsis may benefit from DVT prophylaxis.

KNOWLEDGE GAPS AND RESEARCH OPPORTUNITIES

This report from the SSC pediatric guidelines panel covers five main topic areas (i.e., early recognition and infection, hemodynamics, ventilation, endocrine and metabolic therapies, and adjunctive therapies) with a total of 77 recommendations arising from 67 PICO questions. On review of these evidence-based analyses, it is clear that, for many PICO questions, the literature review failed to identify sufficient data to develop strong (or even weak in some instances) recommendations for critically ill children with septic shock or other sepsis-associated organ dysfunction. These SSC pediatric guidelines, at the same time, also identified gaps that can inform future research opportunities. As new research populates the evidence-base, it can then be used to develop future iterations of the SSC pediatric guidelines, creating a cycle designed to grow the evidence and increase the number of strong recommendations in the future. Further clarity is needed from both informative pathophysiology studies as well as well-designed RCTs, and the panelists have listed these in the text. The design of meaningful and effective future research should be informed by the needs identified by the collective clinical expertise within the panel.

Overall, the process of developing the SSC-pediatric guidelines generated at least 29 pathophysiology questions warranting further study and 23 RCTs (i.e., total of 52 studies). We present these questions as research opportunities, but have not yet prioritized these opportunities into a formal research agenda (**Table 6**). We envision that many of the pathophysiology questions can be taken up by individual research groups, and we hope that the SSC children's guidelines document will serve as a template of current evidence and how best to fill the gaps in our knowledge. In contrast, the necessary RCTs will need a coordinated national/international effort and our community will need to prioritize the most appropriate studies at different phases of management (i.e., recognition, fluid resuscitation, first 48 hr).

ACKNOWLEDGMENTS

We wish to thank Darlene Barkman, MA, and Janna Pogers, PT, MPT, NCS, CSRS for their sensitive and insightful comments from the perspective of parents of children with sepsis. Their input, particularly related to ranking the importance of outcomes to consider through the literature search, provided valuable direction to the panel. We also wish to thank Rebecca Skidmore and James D. Medd for their dedication as they conducted the literature searches for the five panels. Their experience and professionalism contributed greatly to the final publication. Finally, appreciation is extended to Deborah L. McBride for project management and editorial support.

Subgroup	Pathophysiology	Clinical Trials
Blood products: Two pathophysiology studies	Optimal hemoglobin level in children with septic shock or other sepsis-associated organ dysfunction (see Recs 65 and 66) The threshold at which the benefits of platelet transfusion outweigh the risks in children with septic shock or other sepsis-associated organ dysfunction (see Rec 67)	
Plasma exchange, renal replacement, and extracorporeal support: Two pathophysiology studies and two RCTs	Optimal timing and approach for ECMO in refractory shock (see Rec 74) To define optimal pre-ECMO candidacy (see Recs 73 and 74)	Plasma exchange in children with septic shock or sepsis-associated organ dysfunction with thrombocytopenia-associated organ failure (see Rec 70) Renal replacement therapy vs diuretics in the first 48 hr in children with septic shock or other sepsis-associated organ dysfunction (see Recs 71–72)
Immunoglobulins		
Prophylaxis: One RCT		Stress ulcer prophylaxis in relation to feeding in children with septic shock or other sepsis-associated organ dysfunction (see Rec 76)

ECMO = extracorporeal membrane oxygenation, PARDS = pediatric acute respiratory distress syndrome, PEEP = positive end-expiratory pressure, QI = quality improvement, RCT = randomized clinical trial, Rec = recommendation number.

Drs. Weiss and Peters served as arbiters for conflict interest management and adjudication throughout the guidelines process following standard operating procedures set forth by Society of Critical Care Medicine (SCCM) and endorsed by European Society of Intensive Care Medicine. Dr. Weiss participates in Pediatric Acute Lung Injury and Sepsis Investigators (PALISI) and Shock Society. Dr. Peters participates in the UK PICS study group (vice-chair) and has testified as an expert witness in cases of clinical negligence, causation of injuries. Dr. Agus participates in the American Academy of Pediatrics (AAP), Pediatric Academic Societies (PAS), American Pediatric Society, Society for Pediatric Research, and The American Society for Clinical Investigation, and he has testified as an expert witness in cases related to ICU and/or endocrinology in children. Dr. Flori participates in American Thoracic Society (ATS) State Chapter (Executive Board Member—Michigan and California State Chapters) and PALISI Network, Grant funding from Gerber Foundation (Steering committee member for various studies being implemented through the Network for intramural funding, governmental or other Foundation Grant funding). Dr. Nadel received funding from La Jolla Pharmaceutical (consulting), and he participates in the European Society of Pediatric and Neonatal Intensive Care (ESPNIC) (Medical President). Dr. Brierley participates in the ESPNIC. Dr. Carrol participates in National Institute for Health and Care Excellence (NICE) (Diagnostic Advisory Committee panel) and National Institutes for Health Research (two scientific panels, i4i and DTF). Dr. Cheifetz participates in American Association for Respiratory Care and ATS (volunteer activities) and has testified as an expert witness for medical malpractice cases, he is an advisor to Philips, and a contributor to Up-to-Date. Dr. Cies received funding from Allergan, Merck, Thermo Fisher Scientific, and Atlantic Diagnostic Laboratories (consultant), and he participates in Pediatric Pharmacy Advocacy Group (multiple positions), Society of Infectious Diseases Pharmacists (Vice-Chair of the Inter-organizations Liaison Committee), and the American College of Clinical Pharmacists (member and fellow). Dr. Cruz has testified as an expert witness in cases of children with tuberculosis-related meningitis and is an associate editor for *Pediatrics*. Dr. De Luca serves as Medical President-elect on the Executive Committee of ESPNIC, he served as a consultant and lecturer on the external advisory board and received research and educational grants from Chiesi Farmaceutici S.p.A and AbbVie, and travel grants from AbbVie, he has been a lecturer for Philips, Radiometer, and Waire. Dr. Faust served as chair of the UK NICE Guideline Committee for Sepsis in Children and Adults published in 2016 and for Lyme disease

published in 2018, serves as a regional representative to the UK NHS England Clinical Reference Group for commissioning pediatric specialist medicine care (immunology and infection). Dr. Hall receives funding from La Jolla Pharmaceuticals (consultant on the data safety monitoring board for a clinical trial of a sepsis therapeutic), and he participates in the ATS (online journal club editor) and the American Board of Pediatrics (Critical Care Medicine sub-board). Dr. Ishimine participates in SAEM (Consensus Conference Co-Chair), American Board of Pediatrics/American Board of Emergency Medicine (Immediate Past Chair of the Pediatric Emergency Medicine Subboard), and the American College of Emergency Physicians (Pediatric Emergency Medicine Committee member). Dr. Javouhey received funding from CSL Behring (trial on IV Immunoglobulins in toxic shock syndrome in children). Dr. Karam participates in BloodNet, PALISI, ISBT, AABB, and CCCTG. Dr. Kneyber participates in the European Society for Pediatric and Neonatal Intensive Care. Dr. MacLaren participates in Extracorporeal Life Support Organization (Executive Committee). Dr. Mehta participates in the American Society for Parenteral and Enteral Nutrition (resident). Dr. Møller participates in the Science Systems and Applications, Inc (board member). Dr. Newth received funding from Philips Research North America (consulting concerning monitoring in PICU), and he participates in the ATS. Dr. Nishisaki's institutional department receives an unrestricted grant from Nihon Kohden (involves an activity to develop a device to measure capillary refill time), and he participates in the Society for Simulation in Healthcare and International Society for Pediatric Simulation. Dr. Nunnally participates in American College of Critical Care Medicine (Regent), Society of Critical Care Anesthesiologists (director), American Society of Anesthesiologists (committee), International Anesthesia Research Society, and NYSA. Dr. Randolph's institution received funding from Genentech (influenza biomarker study research support); she has received funding from Bristol Myers Squibb (consultant in 2017) and La Jolla Pharmaceuticals (design of pediatric septic shock trial of angiotensin II); and she participates in the ATS and the International Sepsis Forum. Dr. Ranjit participates as the Chancellor of College of Pediatric Critical Care, India. Dr. Tume participates in ESPNIC (Nursing President) and the UK PICS Scientific and Education Committee. Dr. Verger participates in the American Association of Critical-Care Nurses (Cert. Corp. Governance Committee) and the Academy of Nursing (Acute and Critical Care Special Interest Group). Dr. Williams participates in the Pediatric Cardiac Intensive Care Society. Dr. Wolf received funding support for participation in industry-sponsored research from Merck & Co, Astellas,

and Cempra Pharmaceuticals, and he received other support from Karius, Empatica, and Bluespark Technologies. Dr. Zimmerman (Past President of SCCM) received funding from Immunexpress, Seattle (sepsis biomarker research), and he participates in the AAP and PAS. Dr. Tissieres received funding from Baxter acute therapies, Bristol-Myers Squibb Company, Chiesi Farmaceutici S.p.A., Faron Pharmaceuticals (consulting, renal replacement therapy), and Biomerieux, funding from La Jolla Pharmaceuticals, Chiesi Farmaceutici S.p.A., and is President ESPNIC (research grant, biomarkers sepsis), and he participates in the Swiss Intensive Care Society, Swiss Pediatric Society, and the French Society of Intensive Care. The remaining authors have disclosed that they do not have any potential conflicts of interest.

Appendix 1. Summary of Guidelines

SCREENING, DIAGNOSIS, AND SYSTEMATIC MANAGEMENT OF SEPSIS

1. In children who present as acutely unwell, we *suggest* implementing systematic screening for timely recognition of septic shock and other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence). PICO 1
Remarks: Systematic screening needs to be tailored to the type of patients, resources, and procedures within each institution. Evaluation for the effectiveness and sustainability of screening should be incorporated as part of this process.
2. We were unable to issue a recommendation about using blood lactate values to stratify children with suspected septic shock or other sepsis-associated organ dysfunction into low-versus high-risk of having septic shock or sepsis. PICO 2
3. We *recommend* implementing a protocol/guideline for management of children with septic shock or other sepsis-associated organ dysfunction (BPS). PICO 3
4. We *recommend* obtaining blood cultures before initiating antimicrobial therapy in situations where this does not substantially delay antimicrobial administration (BPS). PICO 4

ANTIMICROBIAL THERAPY

5. In children with septic shock, we *recommend* starting antimicrobial therapy as soon as possible, within 1 hour of recognition (strong recommendation, very low quality of evidence). PICO 6
6. In children with sepsis-associated organ dysfunction but without shock, we *suggest* starting antimicrobial therapy *as soon as possible* after appropriate evaluation, within 3 hours of recognition (weak recommendation, very low quality of evidence). PICO 6
7. We *recommend* empiric broad-spectrum therapy with one or more antimicrobials to cover all likely pathogens (BPS). PICO 5
8. Once the pathogen(s) and sensitivities are available, we *recommend* narrowing empiric antimicrobial therapy coverage (BPS). PICO 5
9. If no pathogen is identified, we *recommend* narrowing or stopping empiric antimicrobial therapy according to clinical presentation, site of infection, host risk factors, and adequacy of clinical improvement in discussion with infectious disease and/or microbiological expert advice (BPS). PICO 5
10. In children without immune compromise and without high risk for multidrug-resistant pathogens, we *suggest* against the routine use of empiric multiple antimicrobials directed against the same pathogen for the purpose of synergy (weak recommendation, very low quality of evidence). PICO 8/9
Remarks: In certain situations, such as confirmed or strongly suspected group B streptococcal sepsis, use of empiric multiple antimicrobials directed against the same pathogen for the purpose of synergy may be indicated.
11. In children with immune compromise and/or at high risk for multidrug-resistant pathogens, we *suggest* using empiric multi-drug therapy when septic shock or other sepsis-associated organ dysfunction is present/suspected (weak recommendation, very low quality of evidence). PICO 8/9
12. We *recommend* using antimicrobial dosing strategies that have been optimized based on published pharmacokinetic/pharmacodynamic principles and with consideration of specific drug properties (BPS). PICO 7
13. In children with septic shock or sepsis-associated organ dysfunction who are receiving antimicrobials, we *recommend* daily assessment (e.g., clinical, laboratory assessment) for de-escalation of antimicrobial therapy (BPS). PICO 11
Remarks: This assessment should include a review of the ongoing indication for empiric antimicrobial therapy after the first 48 hours that is guided by microbiologic results and in response to clinical improvement and/or evidence of infection resolution. This recommendation applies to patients being treated with empiric, targeted, and combination therapy.
14. We *recommend* determining the duration of antimicrobial therapy according to the site of infection, microbial etiology, response to treatment, and ability to achieve source control (BPS). PICO 10

SOURCE CONTROL

15. We *recommend* that emergent source control intervention be implemented as soon possible after a diagnosis of an infection amenable to a source control procedure is made (BPS). PICO 12
Remarks: Appropriate diagnostic testing to identify the site of infection and microbial etiology should be performed, and advice from specialist teams (e.g., infectious diseases, surgery) should be sought, as appropriate, in order to prioritize interventions needed to achieve source control.
16. We *recommend* removal of intravascular access devices that are confirmed to be the source of sepsis or septic shock after other vascular access has been established and depending on the pathogen and the risks/benefits of a surgical procedure (strong recommendation, low quality of evidence). PICO 13

FLUID THERAPY

17. In healthcare systems with availability of intensive care, we *suggest* administering up to 40-60 mL/kg in bolus fluid (10-20 mL/kg per bolus) over the first hour, titrated to clinical markers of cardiac output and discontinued if signs of fluid overload develop, for the initial resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 17

18. In healthcare systems with no availability of intensive care and *in the absence of hypotension*, we recommend against bolus fluid administration while starting maintenance fluids (strong recommendation, high quality of evidence). PICO 17

19. In healthcare systems with no availability of intensive care, *if hypotension is present*, we suggest administering up to 40 mL/kg in bolus fluid (10-20 mL/kg per bolus) over the first hour with titration to clinical markers of cardiac output and discontinued if signs of fluid overload develop (weak recommendation, low quality of evidence). PICO 17

Remarks: Clinical markers of cardiac output may include heart rate, blood pressure, capillary refill time, level of consciousness, and urine output. In all settings, the need for fluid administration should be guided by frequent reassessment of clinical markers of cardiac output, serial blood lactate measurement and advanced monitoring, when available. Signs of fluid overload that should limit further fluid bolus therapy may include clinical signs of pulmonary edema or new or worsening hepatomegaly.

20. We *suggest* using crystalloids, rather than albumin, for the initial resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, moderate quality of evidence). PICO 15

Remarks: Although there is no difference in outcomes, this recommendation takes into consideration cost and other barriers of administering albumin compared to crystalloids.

21. We *suggest* using balanced/buffered crystalloids, rather than 0.9% saline, for the initial resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence). PICO 14

22. We *recommend* against using starches in the acute resuscitation of children with septic shock or other sepsis-associated organ dysfunction (strong recommendation, moderate quality of evidence) PICO 16

23. We *suggest* against using gelatin in the resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 16

HEMODYNAMIC MONITORING

24. We were unable to issue a recommendation about whether to target mean arterial blood pressure (MAP) at the 5th or 50th percentile for age in children with septic shock and other sepsis-associated organ dysfunction. PICO 21

25. We *suggest* not using bedside clinical signs in isolation to categorize septic shock in children as “warm” or “cold” (weak recommendation, very low quality of evidence). PICO 20

26. We *suggest* using advanced hemodynamic variables, when available, in addition to bedside clinical variables to guide the resuscitation of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 18

Remarks: Advanced hemodynamic monitoring may include cardiac output/cardiac index, systemic vascular resistance, or central venous oxygen saturation (ScvO₂).

27. We *suggest* using trends in blood lactate levels, in addition to clinical assessment, to guide resuscitation of children with septic shock and other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence). PICO 19

Remarks: In children with an elevated blood lactate, repeat testing that reveals a persistent elevation in blood lactate may indicate incomplete hemodynamic resuscitation and should prompt efforts, as needed, to further promote hemodynamic stability

VASOACTIVE MEDICATIONS

28. We *suggest* using epinephrine, rather than dopamine, in children with septic shock (weak recommendation, low quality of evidence). PICO 22

29. We *suggest* using norepinephrine, rather than dopamine, in children with septic shock (weak recommendation, very low quality of evidence). PICO 23

30. We were unable to issue a recommendation for a specific first-line vasoactive infusion for children with septic shock. PICO 22/23

31. We were unable to issue a recommendation about initiating vasoactive agents through peripheral access in children with septic shock. PICO 26

Remarks: It is reasonable to begin vasoactive infusions after 40-60 mL/kg of fluid resuscitation if the patient continues to have evidence of abnormal perfusion. Either epinephrine or norepinephrine may be administered through a peripheral vein (or intraosseous, if in place) if central venous access is not readily accessible. Dopamine may be substituted as the first-line vasoactive infusion, administered either peripherally or centrally, if epinephrine or norepinephrine is not readily available.

32. We *suggest* either adding vasopressin or further titrating catecholamines in children with septic shock who require high-dose catecholamines (weak recommendation, low quality of evidence). PICO 25

Remarks: No consensus was achieved on the optimal threshold for initiating vasopressin. Therefore, this decision should be made according to individual clinician preference.

33. We were unable to issue a recommendation about adding an inodilator in children with septic shock and cardiac dysfunction despite other vasoactive agents. PICO 24

VENTILATION

34. We were unable to issue a recommendation about whether to intubate children with fluid-refractory, catecholamine-resistant septic shock. PICO 27

35. We *suggest* not to use etomidate when intubating children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 28

36. We *suggest* a trial of non-invasive mechanical ventilation (over invasive mechanical ventilation) in children with sepsis-induced pediatric ARDS (PARDS) without a clear indication for intubation and who are responding to initial resuscitation (weak recommendation, very low quality of evidence). PICO 29 Remarks: When non-invasive mechanical ventilation is initiated, clinicians should carefully and frequently re-evaluate the patient's condition.

37. We *suggest* using high positive end-expiratory pressure (PEEP) in children with sepsis-induced PARDS (weak recommendation, very low quality of evidence). PICO 30

Remarks: The exact level of high PEEP has not been tested or determined in PARDS patients. Some RCTs and observational studies in PARDS have used and advocated for use of the ARDS-network PEEP to fractional inspired oxygen (FiO₂) grid though adverse hemodynamic effects of high PEEP may be more prominent in children with septic shock.

38. We cannot *suggest* for or against the use of recruitment maneuvers in children with sepsis-induced PARDS and refractory hypoxemia. PICO 31 Remarks: If a recruitment maneuver is considered, the use of a stepwise, incremental and decremental PEEP titration maneuver is preferred over sustained inflation techniques that have not been optimized through direct testing in PARDS patients. All PARDS patients must be carefully monitored for tolerance of the maneuver.

39. We *suggest* a trial of prone positioning in children with sepsis and severe PARDS (weak recommendation, low quality of evidence). PICO 32

Remarks: Research trials in adults with ARDS and children with PARDS have emphasized prone positioning for at least 12 hours per day, as tolerated.

40. We *recommend* against the routine use of inhaled nitric oxide (iNO) in all children with sepsis-induced PARDS (strong recommendation, low quality of evidence). PICO 33

41. We *suggest* using iNO as a rescue therapy in children with sepsis-induced PARDS and refractory hypoxemia after other oxygenation strategies have been optimized (weak recommendation, moderate quality of evidence). PICO 33

42. We were unable to issue a recommendation to use high-frequency oscillatory ventilation (HFOV) versus conventional ventilation in children with sepsis-induced PARDS. PICO 34

43. We *suggest* using neuromuscular blockade in children with sepsis and severe PARDS (weak recommendation, very low quality of evidence). PICO 35

Remarks: The exact duration of neuromuscular blockade use in severe PARDS patients has not been determined to date. Most of the adult RCT data and pediatric observational data support treatment for 24-48 hours after ARDS onset.

CORTICOSTEROIDS

44. We *suggest* against using intravenous hydrocortisone to treat children with septic shock if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability (weak recommendation, low quality of evidence). PICO 47

45. We *suggest* that either intravenous hydrocortisone or no hydrocortisone may be used if adequate fluid resuscitation and vasopressor therapy are not able to restore hemodynamic stability (weak recommendation, low quality of evidence). PICO 47

ENDOCRINE AND METABOLIC

46. We *recommend* against insulin therapy to maintain glucose target at or below 140 mg/dL (7.8 mmol/L) (strong recommendation, moderate quality of evidence). PICO 52/60

47. We were unable to issue a recommendation regarding what blood glucose range to target for children with septic shock and other sepsis-associated organ dysfunction. PICO 52/60

48. We were unable to issue a recommendation as to whether to target normal blood calcium levels in children with septic shock or sepsis-associated organ dysfunction. PICO 62
49. We *suggest* against the routine use of levothyroxine in children with septic shock and other sepsis-associated organ dysfunction in a sick euthyroid state (weak recommendation, low quality of evidence). PICO 63
50. We *suggest* either antipyretic therapy or a permissive approach to fever in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, moderate quality of evidence). PICO 64

NUTRITION

51. We were unable to issue a recommendation regarding early hypocaloric/trophic enteral feeding followed by slow increase to full enteral feeding versus early full enteral feeding in children with septic shock or sepsis-associated organ dysfunction without contraindications to enteral feeding. PICO 51
52. We *suggest* not withholding enteral feeding solely on the basis of vasoactive-inotropic medication administration (weak recommendation, low quality of evidence). PICO 48 Remarks: Enteral feeding is not contraindicated in children with septic shock after adequate hemodynamic resuscitation who no longer require escalating doses of vasoactive agents or in whom weaning of vasoactive agents has started.
53. We *suggest* enteral nutrition as the preferred method of feeding and that parenteral nutrition may be withheld in the first 7 days of PICU admission in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, moderate quality of evidence). PICO 49/50
54. We *suggest* against supplementation with specialized lipid emulsions in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence). PICO 53
55. We *suggest* against the routine measurements of gastric residual volumes (GRV) in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 54
56. We *suggest* administering enteral feeds through a gastric tube, rather than a post-pyloric feeding tube, to children with septic shock or other sepsis-associated organ dysfunction who have no contraindications to enteral feeding (weak recommendation, low quality of evidence). PICO 55
57. We *suggest* against the routine use of prokinetic agents for the treatment of feeding intolerance in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 56
58. We *suggest* against the use of selenium in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 57
59. We *suggest* against the use of glutamine supplementation in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 58
60. We *suggest* against the use of arginine in the treatment of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence). PICO 59
61. We *suggest* against using zinc supplementation in children with septic shock and other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence). PICO 61
62. We *suggest* against the use of ascorbic acid (vitamin C) in the treatment of children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence). PICO 65
63. We *suggest* against the use of thiamine to treat children with sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 66
64. We *suggest* against the acute repletion of vitamin D deficiency (VDD) for treatment of septic shock or other sepsis-associated organ dysfunction (weak recommendation, very low quality of evidence). PICO 67

BLOOD PRODUCTS

65. We *suggest* against transfusion of red blood cells if the blood hemoglobin concentration is ≥ 7 g/dL in hemodynamically stabilized children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 38 Remarks: According to the 2018 Transfusion and Anemia Expertise Initiative (TAXI) guidelines, for the purposes of red blood cell transfusion, "hemodynamically stabilized" is defined as a mean arterial blood pressure higher than 2 standard deviations below normal for age and no increase in vasoactive medications for at least 2 hours.
66. We cannot make a recommendation regarding hemoglobin transfusion thresholds for critically ill children with unstable septic shock. PICO 38
67. We *suggest* against prophylactic platelet transfusion based solely on platelet levels in non-bleeding children with septic shock or other sepsis-associated organ dysfunction and thrombocytopenia (weak recommendation, very low quality of evidence). PICO 40

68. We *suggest* against prophylactic plasma transfusion in non-bleeding children with septic shock or other sepsis-associated organ dysfunction and coagulation abnormalities (weak recommendation, very low quality of evidence). PICO 39 Remarks: Prophylactic plasma transfusion refers to situations in which there is an abnormality in laboratory coagulation testing but no active bleeding.

PLASMA EXCHANGE, RENAL REPLACEMENT, AND EXTRACORPOREAL SUPPORT

69. We *suggest* against using plasma exchange in children with septic shock or other sepsis-associated organ dysfunction without thrombocytopenia-associated multiple organ failure (TAMOF) (weak recommendation, very low quality of evidence). PICO 37

70. We cannot suggest for or against the use of plasma exchange in children with septic shock or other-sepsis-associated organ dysfunction with TAMOF. PICO 37

71. We *suggest* using renal replacement therapy to prevent or treat fluid overload in children with septic shock or other sepsis-associated organ dysfunction who are unresponsive to fluid restriction and diuretic therapy (weak recommendation, very low quality of evidence). PICO 43

72. We *suggest* against high-volume hemofiltration over standard hemofiltration in children with septic shock or other sepsis-associated organ dysfunction who are treated with renal replacement therapy (weak recommendation, low quality of evidence). PICO 44

73. We *suggest* using veno-venous (VV) extracorporeal membrane oxygenation (ECMO) in children with sepsis-induced PARDS and refractory hypoxia (weak recommendation, very low quality of evidence). PICO 36

74. We *suggest* using veno-arterial (VA) ECMO as a rescue therapy in children with septic shock only if refractory to all other treatments (weak recommendation, very low quality of evidence). PICO 45

IMMUNOGLOBULINS

75. We *suggest* against the routine use of intravenous immune globulin (IVIG) in children with septic shock or other sepsis-associated organ dysfunction (weak recommendation, low quality of evidence). PICO 46 Remarks: Although routine use of IVIG is not recommended, select patients may benefit from such treatment.

PROPHYLAXIS

76. We *suggest* against the routine use of stress ulcer prophylaxis in critically ill children with septic shock or other sepsis-associated organ dysfunction, except for high-risk patients (weak recommendation, very low quality of evidence). PICO 41

Remarks: Although *routine* stress-ulcer prophylaxis is not recommended, some high-risk patients may benefit from stress ulcer prophylaxis. Studies have supported benefit of stress ulcer prophylaxis when baseline rate of clinically important bleeding is approximately 13%.

77. We *suggest* against routine deep vein thrombosis (DVT) prophylaxis (mechanical or pharmacologic) in critically ill children with septic shock or other sepsis-associated organ dysfunction, but potential benefits may outweigh risks and costs in specific populations (weak recommendation, low quality of evidence). PICO 42
